Although suppurative arthritis is the most common manifestation of gonococcal sepsis involving the skeletal system [84], osteomyelitis is associated with sepsis as well and probably represents the site of primary infection in many cases [38,85,86]. Syphilitic osteitis and osteochondritis, although frequent in former years [87], have been largely eliminated through serologic detection of disease during routine antenatal testing and institution of appropriate therapy for infected mothers. An increase in the incidence of syphilis among women of childbearing age has been reflected in a parallel increase in the frequency of neonatal syphilis and attendant problems of treponemal bone infection [88,89].

*Mycoplasma* and *Ureaplasma* have been reported as rare causes of osteomyelitis in infants. In one infant, bone infection caused by *Mycoplasma hominis* developed in a sternotomy wound after cardiac surgery [90]; in another infant weighing 900 g with osteomyelitis of the hip and femur, the infection was caused by *Ureaplasma urealyticum* [91]. Tuberculous osteomyelitis is extremely rare in neonates, even in the presence of disseminated congenital tuberculosis [92,93]. Among a group of infants with widespread disease acquired in the perinatal or neonatal period, the youngest with skeletal involvement was 3 months of age [86].

## PATHOGENESIS

Complications of pregnancy, labor, or delivery may precede the occurrence of neonatal osteomyelitis in one half of patients.* Most bone and joint infections occur in a small or premature infant as a result of prolonged nosocomial exposures and multiple invasive procedures. Although anoxia (as from placenta previa, breech extraction, or fetal distress) or exposure to microorganisms (from premature rupture of membranes) can explain this association in some cases, the means whereby maternal or obstetric problems influence the likelihood of acquiring bone infection is generally unknown.

Microorganisms may reach the skeletal tissues of the fetus and newborn in one of four ways: (1) by direct inoculation, (2) by extension from infection in surrounding soft tissues, (3) as a consequence of maternal bacteremia with transplacental infection and fetal sepsis, and (4) by blood-borne dissemination in the course of neonatal septicemia. Although hematogenous dissemination is responsible for most cases, examples of other routes of infection have appeared occasionally in the literature. As noted previously (see "Microbiology"), other factors, such as preceding urinary tract infection or direct translocation of bacteria across the bowel wall, may explain bone or joint infection in some neonates.

Direct inoculation of bacteria resulting in osteomyelitis has followed femoral venipuncture [36,59,69,94–96], radial artery puncture [30], use of a fetal scalp monitor [14,97–100], great toe [84] or heel [14,30,31,101–105] capillary blood sampling [106], and serial lumbar punctures [107]. Infection after surgical invasion of bony structures (e.g., median sternotomy for cardiac surgery) is uncommon [108]. Nevertheless, trauma has been associated with osteomyelitis of the neonate (an association that has been noted for osteomyelitis in older children); *S. aureus* osteomyelitis has occurred in a neonate at 3 weeks of age at the site of a perinatal fracture of the clavicle [109].

Osteomyelitis caused by extension of infection from surrounding soft tissues usually is associated with organisms from an infected cephalhematoma involving the adjacent parietal bone [98,110–112]. A series of patients with *S. aureus* osteomyelitis of the skull associated with overlying scalp abscesses was reported in 1952 [113]. Predisposing factors in these patients were thought to be prolonged, excessive pressure on the fetal head when it lay against the sacral promontory or symphysis pubis, secondary ischemic necrosis, and localization of infection. Paronychia during the newborn period, although most frequently a source of sepsis and hematogenous dissemination of organisms, may extend into bony structures and cause phalangeal infection [47].

Transplacental bacterial bone infection is most characteristic of syphilis (see Chapter 16). A rare exception, published as a case report in 1933, described a premature infant who died at 19 hours of age with evidence of subacute parietal bone osteomyelitis, meningitis, and cerebritis. Rupture of the amniotic sac immediately before delivery, histopathologic evidence of the prolonged course (at least 2 weeks) of the infection, and the lack of involvement of the overlying scalp epidermis indicate that despite apparent absence of maternal illness, this infant was infected transplacentally. The authors postulated that a primary infection occurred in the parietal bone, with secondary extension to the meninges and brain. Although organisms were not isolated, gram-positive diplococci were identified in infected tissues [114].

Blood-borne dissemination of organisms, with metastatic seeding of the skeletal system through nutrient arteries, is the major cause of neonatal osteomyelitis [48,115]. Before the advent of antibiotics, the long bones reportedly became infected in 10% of infants with bacteremia [47,116]. Since that time, early recognition and effective empirical therapy for bacterial sepsis led to a marked decrease in the incidence of this complication. Candidal invasion of the bloodstream has become a more frequent cause of bone and joint infections in small infants (see Chapter 33).*

*References [11,13,16,19,30,38–40].

*References [20,22,23,33,117,118].

The use of intravascular catheters frequently has been associated with bacterial and fungal osteomyelitis in neonates.* Septic embolization occurs from infected catheter-tip thrombi, producing relatively high-grade bacteremias; local hypoxia from partial occlusion of vessels by the catheter may also contribute to bone infections [12,119]. The most common etiologic agent has been *S. aureus*, but other microorganisms, such as *Klebsiella* [73], *Proteus* [64], *Enterobacter* [74,75], and *Candida* [20,22,66,117], have also been implicated. Because the iliac arteries are the most likely pathway for an arterial embolus originating in an aortic catheter tip, the hips or knees or both are involved in more than three fourths of patients.† There is a very close correlation between the site of the catheter and localization of osteomyelitis in the ipsilateral leg [12]. The distribution of infection originating in umbilical vein catheters is less predictable [22,74,117,121–123]. The incidence of osteoarthritis varies greatly, ranging from 1 in 30[119] to less than 1 in 600[12] infants with umbilical artery catheters; it can be reduced significantly by proper attention to aseptic technique and careful monitoring of catheter placement combined with prompt catheter removal whenever possible [12].

The disseminating focus of a bacteremia-producing metastatic abscess in bones is often unknown. Common primary sources include omphalitis,* pustular dermatitis,† purulent rhinitis [5,55,124], paronychia,‡ and mastitis [4,49]. In a few infants, sepsis with subsequent osteomyelitis has arisen from infected circumcisions [8,36], operative sites [8,31,69], intramuscular injections [49,69], or varicella lesions [11]. Although gonococcal osteoarthritis originates most commonly from a purulent conjunctivitis, virtually any orifice may provide a portal of entry [84].

Hematogenous infection of long bones is initiated in dilated capillary loops of the metaphysis, adjacent to the cartilaginous growth plate (physis), where blood flow slows, providing pathogenic bacteria with an ideal environment to multiply, resulting in abscess formation (Fig. 8–1) [115,125,126]. When the infectious process localizes at this site, the following sequence may occur: (1) direct invasion and lysis of the cartilaginous growth plate; (2) spread from metaphyseal vessel loops into transphyseal vessels coursing through the growth plate and into epiphyseal vessels; or (3) rupture occurring laterally, through the cortex into the joint, subperiosteal space, or surrounding soft tissues [125,126]. The large vascular spaces and thin spongy structure of metaphyseal cortex in infants permit early decompression of this primary abscess into the subperiosteal space [48,56]. For this reason, the bone marrow compartment is seldom involved in neonates, and the term osteitis is probably more accurate than osteomyelitis.

After rupture into the subperiosteal space, the abscess dissects rapidly beneath loosely attached periosteum, often involving the entire length and circumference of the bone. As pressure increases from accumulating pus,

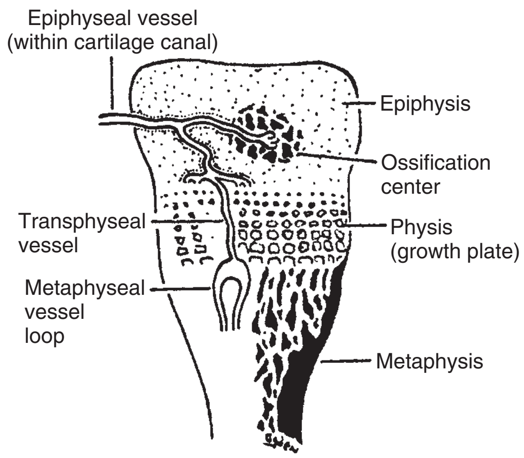

**FIGURE 8–1 Schematic depiction of blood supply in the neonatal epiphysis.** In children, normally there are two separate circulatory systems: (1) the metaphyseal loops, derived from the diaphyseal nutrient artery, and (2) the epiphyseal vessels, which course through the epiphyseal cartilage within structures termed cartilage canals. In the neonatal period, sinusoidal vessels, termed transphyseal vessels, connect these two systems. With ensuing skeletal maturation, these vessels disappear, and the epiphyseal and metaphyseal systems become totally separated. *(From Ogden JA, Lister G. The pathology of neonatal osteomyelitis. Pediatrics 55:474, 1975.)*

there may be decompression through the thin, periosteal tissue into surrounding soft tissues, and a subcutaneous abscess may form. In the absence of surgical intervention, collected pus "points" and drains spontaneously through the skin, forming a sinus tract. When adequate decompression and drainage have been established, general supportive care often is sufficient to permit complete healing and resolution of osseous and soft tissue foci of infection [46,48,127,128]. Free communication between the original site of osteomyelitis and the subperiosteal space prevents the necrosis and extensive spread of infection through the bone shaft that occurs frequently in older children and adults. Cortical sequestra are less common in infants, and because of the extreme richness of the newborn bone blood supply, sequestra often are completely absorbed if they do form [48]. In addition, the efficient vasculature and fertility of the inner layer of the periosteum encourage early development of profuse new bone formation (involucrum), permitting remodeling of bone within a very short time after the infectious process has been controlled [48,115].

The same characteristics of neonatal bone that serve to prevent many of the features of chronic osteomyelitis seen in older children are also responsible for complications occurring in neonates and young infants, such as epiphysitis and pyarthrosis. A consequence of the excellent bone blood supply in newborns is persistent fetal vessels that penetrate the cartilaginous epiphyseal plate and end in large venous lakes within the epiphysis [115,125,126]. Localization of organisms at these sites early in the course of osteomyelitis leads to an epiphysitis, with resultant severe damage of the cartilage cells on the epiphyseal side of the growth plate. When such damage occurs, it is generally irreparable [70,115] and ultimately results in arrest or disorganization of growth at the ends of the bone. By age 8 to 18 months, the vascular connections between

‡References [4,5,37,52,55,69,124].

metaphysis and epiphysis are obliterated, and the cartilaginous growth plate provides a barrier against the spread of infection that persists throughout childhood and adult life [115,125,126].

Rapid decompression of the primary metaphyseal abscess through the adjacent cortex also permits ready entrance of pus into the articular space of the bones whose metaphyses lie within the articular capsule of the joint. Suppurative arthritis of the hips, shoulders, elbows, and knees is frequently associated with osteomyelitis of the humerus or femur in infants.* When the infection originates in the epiphysis, pyarthrosis also may occur by direct extension of the primary abscess through the articular cartilage and into the joint space. When pus enters the joint, it causes distention of the joint capsule, and the increasing pressure may eventually produce a pathologic dislocation, particularly of the shoulder or hip joint. The lytic action of pyogenic exudate within the joint [129,130] and ischemia produced by the high intra-articular tension often are sufficient to cause dissolution or separation of the entire head of the femur or humerus, both of which are composed almost completely of cartilage during the neonatal period [3,34,35,131–133]. Although serious growth disturbances and deformities may result from septic arthritis at other sites, complete destruction of the joint is rare.

## CLINICAL MANIFESTATIONS

Two distinct clinical syndromes that may be associated with suppurative bone involvement in the newborn period are: (1) a benign form, with little or no evidence of infection (other than local swelling) or disability, related to an osteomyelitis involving one or more skeletal sites, and (2) a severe form, with systemic manifestations of sepsis predominating until multiple sites of bone and visceral involvement are noted as manifestations of the infant's underlying condition [3,37,134]. The most likely cause of the benign form of neonatal osteomyelitis is a mild, transient bacteremia that arises peripherally and causes only minimal inflammation and suppuration. The experience of most investigators indicates that this form of illness represents most cases.* The few series in which high fever and evidence of sepsis were noted as common presenting signs probably represent instances in which diagnosis was delayed, resulting in more advanced disease at presentation [2,3,39,49].

Infants with mild illness generally feed well, gain weight, and develop normally. Systemic manifestations are minimal, and the temperature is usually normal or only slightly elevated.* The diagnosis may be missed until 2 to 4 weeks have elapsed, by which time bone destruction may be severe and widespread [47,54,56,136]. Even in intensive care nurseries, where infants are under continuous professional observation, osteomyelitis may be missed for days or weeks. Bone involvement may be discovered during a skeletal survey or computed tomography (CT) or magnetic resonance imaging (MRI) as an unsuspected site or sites of infection in an infant without known bone involvement; osteomyelitis also has been diagnosed as an incidental finding on chest or abdominal radiographs [16,22,137].

*References [3,4,6,11,13,16,19,20,35,58,134,137–141].

*References [4,6,11,13,14,16,19,31,32,38,40,51,56,135,136].

*References [4,14,31,32,56,131,135].

The first signs that may be noted by parents or physicians are diffuse edema and swelling of an extremity or joint, usually without discoloration, accompanied by excessive irritability of the infant. Handling the infant causes increased discomfort, and prolonged episodes of crying may be noted during after a diaper change or other physical manipulations of routine care. Examination reveals diminished spontaneous and reflex movement of the affected extremity, either because of pain (pseudoparalysis)* or because of weakness caused by an associated neuropathy [138–141]. Pyarthrosis of the hip joint is characterized by maintenance of the hip in a flexed, abducted, and externally rotated (frog-leg) position [138]. Because the slightest degree of passive motion of an extremity may cause severe pain and prolonged crying, attempts to elicit a point of maximal bone tenderness are often unsuccessful.

As the suppurative process extends through the metaphyseal cortex into the surrounding subperiosteal and subcutaneous tissues, external signs of inflammation become more intense, and points of maximal swelling, redness, and heat are more readily discernible. In most cases, an inflammatory mass is directly adjacent to the involved metaphysis or joint, although when deeper skeletal structures (e.g., vertebrae or pelvis) are involved, the abscess may point in distant sites. Three infants have been described in whom vertebral osteomyelitis was not discovered, or even suspected, until after a large retroperitoneal abscess had developed [6]. An abscess arising from the proximal femur, ilium, or hip joint appears usually in the upper thigh, on the buttocks, or in the groin, but occasionally also in the iliac fossa, where it can be palpated through the abdominal wall or rectum [51]. Even when infection is localized in the distal extremities, it is difficult to determine solely on clinical grounds whether the bone or adjacent joint or both are involved. Radiologic examinations and diagnostic aspiration of suspected joints are generally necessary to establish a diagnosis.

The striking feature of the benign form of neonatal osteomyelitis is the satisfactory general condition of the infant, despite the intensity of the local process; feeding and weight gain are undisturbed, and there is no evidence of involvement of visceral structures. Although deformity and disability may follow such infections, the fatality rate is exceedingly low, and healing is prompt.

By contrast, signs and symptoms of the severe form of neonatal osteomyelitis are predominantly those of a septic process with prolonged and intense bacteremia. Infants with this condition usually exhibit failure to thrive, with associated lethargy, refusal or vomiting of feedings, abdominal distention, jaundice, and other signs characteristic of sepsis in the newborn. Infection of the bones and joints may be noted almost simultaneously with onset of septicemia, or it may appear later, despite administration of antibiotics. The clinical evolution of the osteomyelitic process is identical to that in patients with the benign form of the disease. Early localizing signs and symptoms

*References [19,31,32,40,68,72,126].

are frequently overshadowed by the systemic manifestations occurring in the infant. Evidence of a suppurative process in the bone may be discovered accidentally in the course of routine radiographic examinations, or it may not be apparent until formation of a local subcutaneous abscess directs attention to the underlying bone. The prognosis for these infants is guarded; death is generally caused by sepsis, with widespread and multiple foci of infection in the nervous system or viscera. The prognosis for the skeletal lesions among survivors is not different, however, from the prognosis for the benign form.

As group B streptococcal infections have become increasingly prevalent, a distinctive clinical picture associated with osteomyelitis has emerged for GBS [19,31,58,142–146]. Most cases are caused by the type III serotype of streptococci and manifest as a late-onset illness during the 3rd and 4th weeks of life (mean age at diagnosis 25 days). Predisposing factors commonly seen with osteomyelitis caused by other agents, such as maternal obstetric complications, difficulties in the early neonatal period, use of vascular catheters, or other manipulative procedures, are unusual with group B streptococcal disease. The male preponderance usually identified with neonatal osteomyelitis is reversed, with females more affected in a ratio of 1.5:1. In almost 90% of the infants described with this condition, only a single bone has been involved, most commonly the humerus (50%) or femur (33%), affecting the shoulder or knee. In most cases, infants manifest the benign form of osteomyelitis without signs of systemic toxicity or involvement of other organ systems. Nevertheless, most are ill no more than 3 or 4 days before the diagnosis is established. Although affected joints are typically neither warm nor erythematous, local swelling, tenderness, and diminished movement of the affected extremity are usually severe enough for parents to seek early medical attention.

The distribution of bone involvement reported in the literature is shown in Table 8–1, with 741 infected sites among 485 patients. A single bone was involved in 324 patients, and multiple foci were involved in 161 patients (33%) [147,148]. Because radiographic or radionuclide skeletal surveys, which often identify unsuspected foci of osteomyelitis,* were generally not performed, the number of infants reported to have infection in multiple sites is probably falsely low. The high incidence of infections of the femur, humerus, and tibia in neonates has also been noted in adults [150] and older infants and children [8,10,135,151]. The relatively large number of cases of maxillary osteomyelitis is unique, however, to the newborn period; this entity is discussed separately later on.

The exuberant new bone formation associated with osteomyelitis in the newborn period makes it difficult to determine the original foci of infection when radiographs are obtained late in the clinical course. For this reason, either the site of primary metaphyseal abscess was unspecified, or the infection was referred to as a "panosteitis" in many instances. In the femur, proximal, distal, and uncertain sites of early infection are equally distributed, whereas localization in the tibia and humerus occurs most often at proximal ends of bones; in the radius, distal osteomyelitis predominates. The major consequence of these patterns of infection is the high incidence of secondary purulent arthritis of the hips, shoulders, knees, and wrists; this secondary arthritis has been noted in virtually every large series of newborns with bone infection.

**Of infants, 33% had disease in more than one bone.*

## PROGNOSIS

From 1920-1940, reports of neonatal osteomyelitis cited mortality rates of 40% in neonates and young infants [48], but stressed an overall benign nature of the disease and the good prognosis for life and function if sepsis was not present [46,48,127,128]. The introduction of antimicrobial agents effective against the common infecting organisms was associated with a considerable

reduction in mortality rates. Only 24 deaths (mortality rate 4.2%) were reported among approximately 575 newborns with osteomyelitis acquired from 1945-1990.*

The improved survival rate directed greater attention to a high incidence of residual joint deformities after neonatal osteomyelitis, particularly with hip and knee involvement or delayed diagnosis for more than 3 or 4 days.* Destruction or separation of the capital femoral epiphysis may result in serious disturbances of growth, usually combined with a marked coxa vara, valga, or magna; an unstable hip joint; flexion contractures; and abnormalities of gait.† Damage to the cartilaginous growth plate in the knees also is often followed by disturbances in longitudinal growth and angulation at the site of infection, leading to genu varum or valgum, restricted motion, and instability of the joint.‡ Although the consequences of shortening of bone and angular deformities are more serious in lower extremities, analogous growth disturbances may follow osteomyelitis of the humerus, radius, or ulna.§ Most of these data have been collected from infants with staphylococcal bone or joint infection; in contrast, the prognosis for full recovery is excellent after group B streptococcal infection [19,58].

Although vertebral osteomyelitis in the newborn is unusual, the consequences can be grave. Collapse or complete destruction of one or more vertebral bodies may occur [13,22,156–160], with severe kyphosis or paralysis caused by spinal cord compression appearing as late complications [13,156,157]. In most cases, vertebral involvement is not recognized until after paraspinal abscesses appear [6,161–163].

The full clinical consequences of osteomyelitis in the newborn period may not be apparent for months to years. Despite a seemingly favorable outcome, even infants with minor bone or joint involvement should be followed to skeletal maturity to observe for the appearance of late deformity, dysfunction, or growth arrest [69,70]. Early evidence of skeletal destruction frequently requires multiple orthopedic procedures to stabilize a joint or to straighten a limb or equalize its length with that of the contralateral arm or leg. Descriptions of late regeneration of femoral epiphyses despite severe injury emphasize the remarkable healing potential and unpredictability of this illness, however [164–170].

Chronic osteomyelitis and sequestration of necrotic bone have been thought to be uncommon complications before and after the availability of antibiotic therapy.* The apparent rarity of these complications in former years should be questioned, however, because in approximately 10% of infants with osteomyelitis who were studied by several groups of investigators, formation of sequestra occurred, and in many cases, sequestrectomy was required for complete cure.† A rare complication of neonatal osteomyelitis is osteochondroma (or exostosis) at the distal ulna after *S. aureus* osteomyelitis [170].

## DIAGNOSIS

Plain film radiographs remain the most useful means of establishing the diagnosis of neonatal osteomyelitis. Experience with CT and MRI in the evaluation of neonatal bone infection is increasing, and use of these modalities is limited only by the ability to transport small neonates to facilities for imaging and the need for monitoring of anesthetized infants. CT and MRI may be used if plain radiographs, ultrasonography (of joints), and bone scans have not yielded a diagnosis [171].

The earliest radiographic sign is swelling of soft tissue around the site of primary infection. Although this finding reflects spreading edema and inflammation that occur as pus breaks through metaphyseal cortex, it is nonspecific and serves only to define an area of inflammation. The first distinct evidence of bone involvement appears as small foci of necrosis and rarefaction, most commonly located in the metaphysis adjoining the epiphyseal growth plate; this may be accompanied by capsular distention or widening of the joint space if inflammatory exudate or pus has entered the articular capsule. In contrast to older children, in whom radiographic changes are commonly delayed for 3 weeks [10,151], neonates almost always show definite signs of bone destruction after only 7 to 10 days.*

Extension of the suppurative process often produces widespread areas of cortical rarefaction, which, despite their appearance, infrequently result in significant bone sequestration. The presence of pus in the hip and shoulder joints may cause progressive lateral and upward displacement of the head of the femur [32,132,133,172] or humerus through stages of subluxation to pathologic dislocation. The absence in the newborn period of ossification centers, with the exception of those at the distal femur and proximal tibia, makes it very difficult to diagnose neonatal epiphysitis in any area but the knees [155]. For similar reasons, epiphyseal separation or destruction of the head of the femur or humerus is difficult to distinguish radiologically from simple dislocation [132,133].

In most infants, the reparative phase begins within 2 weeks after onset of infection. The first sign of healing is the formation of a thin layer of subperiosteal bone, which rapidly enlarges to form a thick involucrum between the raised periosteum and the cortex. Although bone destruction may continue at the same time, necrotic foci are rapidly absorbed and filled in as new bone is deposited. The entire process from the first signs of rarefaction to restoration of the cortical structure may last no longer than 2 months; however, several months usually elapse before minimal deformities disappear and remodeling of the shaft is complete. In some cases, well-circumscribed defects involving the metaphysis and epiphysis may persist for years [155].

The benefit of using radiologic skeletal surveys in newborns with osteomyelitis should be emphasized, particularly because the occurrence of multiple sites of osteomyelitis is much more common in the neonatal period. Clinically unsuspected sites of infection can be discovered

*References [5,11,12,19,38,53,55,149,169].

in a significant proportion of infants.* Demonstration of such lesions may be provide therapeutic benefits. In one series [16], 4 of 7 areas of occult infection required aspiration or drainage, whereas in another study [13], 3 of 17 hip joint infections were discovered on routine radiographs taken because the infant had osteomyelitis elsewhere. Plain film skeletal surveys for occult bone and joint infection are recommended in any infant with osteomyelitis.

As mentioned, experience with CT and MRI in the diagnosis of neonatal musculoskeletal infection is limited [174,175]. Although both procedures can be helpful adjuncts to clinical diagnosis and conventional radiography, they are slow and require heavy sedation—usually undesirable in a febrile septic infant—to prevent movement artifact and loss of resolution. CT provides good definition of cortical bone and is sensitive for early detection of bone destruction, periosteal reaction, and formation of sequestra. It has been used to particular advantage in diagnosis of osteomyelitis of the skull associated with infected cephalhematoma [110,111]. Plain radiographs of uninfected cephalhematomas can show soft tissue swelling, periosteal elevation, calcification, and even underlying radiolucency caused by bone resorption [176]—findings also consistent with bone infection. In such cases, CT has been able to define foci of bone destruction more accurately, helping to confirm the presence of osteomyelitis.

MRI is of limited value in defining structural changes in cortical bone, but it provides excellent anatomic detail of muscle and soft tissue, superior to that of any other imaging technique [175]. It is particularly useful in showing the early soft tissue edema seen adjacent to areas of bone involvement before the appearance of any osseous changes. MRI is also helpful in determining the presence of a periosteal abscess and assessing the need for surgical drainage. The major advantage of MRI over CT is the ability to detect inflammatory or destructive intramedullary disease. It is of greater advantage in older children and adults than in neonates, however, because involvement of the marrow compartment is uncommon in neonates. Both modalities provide excellent spatial resolution and anatomic detail; however, CT is best suited to cross-sectional views, whereas MRI can display anatomy with equal clarity in coronal and sagittal planes, permitting visualization in the plane most advantageous for accurate diagnosis. Absence of ionizing radiation is another distinct advantage of MRI over CT.

There has been increasing interest in the use of ultrasonography to detect bone infection and joint effusions [177–181]. Diagnosis of osteomyelitis is based on periosteal thickening or the presence of abscess formation as indicated by periosteal elevation and separation from bone. The exact role of ultrasonography in diagnosis of neonatal osteoarthritis has continued to be defined. It currently seems most useful as a tool for defining the presence of fluid collections in joints or adjacent to bone and as a guide for needle aspiration or surgical drainage of these collections. The occurrence of false-positive or false-negative examinations, although infrequent, requires that infants with conflicting clinical findings be evaluated further by other techniques. Reports of successful diagnosis of osteomyelitis in neonates with ultrasonography include the diagnosis of rib infection in a 650-g infant with staphylococcal osteomyelitis [182]. Other series have included 2- to 6-week-old infants with osteomyelitis of the costochondral junction and ribs [183,184].

Despite reports emphasizing the reliability of technetium-99m bone imaging in older infants and children [185], experience with the use of this technique in neonates has been far less favorable [16,33,40,149,186–190]. In one study, among 10 newborns subsequently proved to have osteomyelitis involving 20 sites in all, only 8 of these sites were found to be abnormal or equivocal by technetium-99m scan [186]. Of the 12 sites that were normal by technetium-99m scan at 1 to 33 days (mean 8 days) after onset of symptoms, 9 showed destructive changes in the corresponding radiograph. The increased radioactivity in areas of inflammatory hyperemia surrounding an osteomyelitic lesion, usually present in the early "blood-pool" images in children [187], also was not seen, even in infants with ultimately positive delayed bone scans. Although false-negative bone scans also have been described in older infants [191,192], the reason for the excessively high incidence among neonates is unknown. It has been suggested that the discrepancy is due either to differences in the pathophysiology of neonatal disease or to the inability of earlier gamma cameras to separate the increased activity of the growth plate in the first weeks of life from that of infection [137,185].

As indicated by clinical studies, use of newer high-resolution cameras combined with electronic magnification may provide greater diagnostic accuracy [137]. However, In these studies, the investigators also used significantly (fourfold to sixfold) larger doses of technetium-99m, and almost all sites of involvement had radiographically detectable lesions at the time of diagnosis. It seems reasonable at the present time to limit the use of technetium-99m radionuclide scans to evaluation of infants with normal or equivocal radiographs in whom there is a strong clinical suspicion of osteomyelitis.

Among older patients, gallium-67 bone imaging has been shown to be valuable when results of the technetium-99m scan and appearance on plain films are normal and osteomyelitis is strongly suspected [192]. Studies performed in small infants and neonates have shown similar results [191,193]. The radiation burden of this isotope is high, however, and the probability that the results of a scan by themselves would influence therapy is low. The role of gallium-67 bone imaging in the diagnosis of neonatal bone and joint infections is very limited.

Needle aspiration of an inflammatory area may provide a rapid diagnosis [19,31,38,40]. Differentiation of subcutaneous from subperiosteal infection often is difficult; however, significant accumulations of pus aspirated from a periarticular abscess almost invariably are found to originate in bone rather than in the soft tissues [2,126]. Clinical or radiologic evidence of joint space infection, particularly in the hip and shoulder, requires immediate confirmation by needle aspiration. If no effusion is found and clinical signs persist, aspiration should be repeated within 8 to 12 hours. If there is doubt about whether the joint was actually entered, limited arthrography with

*References [13,16,22,33,149,173].

small amounts of dye can readily be performed with an aspirating needle [132,133]. Most iodinated contrast materials do not interfere with bacterial growth from aspirated specimens [194]. Inserting a needle into the metaphyseal region or joint 24 hours before scanning does not interfere with the scintigraphic detection of osteomyelitis [188–190].

The total peripheral white blood cell count is of little value in diagnosing neonatal osteomyelitis. In more than 150 cases in which these values were recorded, median peripheral leukocyte count was approximately 17,000 cells/mm$^3$ (mean 20,000 cells/mm$^3$, range 4000 to 75,100 cells/mm$^3$). Polymorphonuclear leukocytes usually represented about 60% of the white blood cells counted; frequently, the number of immature forms was higher than normal. Neonates with osteomyelitis usually have an erythrocyte sedimentation rate higher than 20 mm/hr.* Similar to leukocyte count, erythrocyte sedimentation rate is helpful for diagnosis and follow-up evaluation when elevated, but cannot be used to rule out osteomyelitis when normal [11,13,14,195]. Alternatively, C-reactive protein is more useful than erythrocyte sedimentation rate as an acute-phase reactant in neonates, and most methods for C-reactive protein determination require only 0.1 mL of blood, as opposed to erythrocyte sedimentation rate, which may require 1 to 2 mL of blood.

## DIFFERENTIAL DIAGNOSIS

The early descriptions of pyogenic neonatal osteomyelitis emphasized difficulties in distinguishing the pseudoparalysis and irritability that are characteristic of this condition from the symptoms of congenital syphilis and from true paralysis of congenital poliomyelitis [196–198]. The clinical course and radiologic examinations are generally sufficient to rule out polio and other neuroparalytic illnesses; however, the periostitis and metaphyseal bone destruction that accompany congenital syphilis are frequently indistinguishable from bone alterations observed in infants with multicentric pyogenic osteomyelitis (see Chapter 16) [154,156]. Similar osseous changes have been noted at birth in infants with congenital tumors or leukemia [196,199].

Serial radiologic examinations may be necessary to distinguish a superficial cellulitis, subcutaneous abscess, or bursitis [200,201] from a primary bone infection, particularly when these conditions arise in a periarticular location. Similarly, a suppurative arthritis arising in the joint space rather than in the adjacent metaphysis can be defined as such only by determining that no destruction has occurred in bones contiguous to that joint.

The relative lack of any inflammatory sign other than edema is the only clinical feature that helps to differentiate between candidal and bacterial osteomyelitis [20,22]. *Candida* infections have been observed more frequently in recent years, particularly in premature infants, in whom antibiotic therapy, placement of umbilical catheters, and use of parenteral hyperalimentation, together with immature host defense mechanisms, predispose to candidal infection and dissemination.* The lesions of *Candida albicans* infection typically are seen as well-defined ("punched-out") metaphyseal lucencies on radiographs, but are less aggressive in appearance than the lesions of staphylococcal osteitis and often are surrounded by a slightly sclerotic margin.† Even when characteristic clinical circumstances and radiographic features are present, the diagnosis in almost all cases rests on identification of the organism by Gram stain or culture, although *Candida* organisms are frequently present concomitantly in blood cultures obtained during febrile episodes.

Several congenital viral lesions have also been associated with bone changes. Lesions caused by congenital rubella, although generally seen in the metaphyseal ends of the long bones, are distinct from the lesions of bacterial osteomyelitis during the early stages of pathogenesis and show no evidence of periosteal reaction during the reparative phase [205]. There is little likelihood of confusion of the radiographic features of bone pathology resulting from congenital cytomegalic inclusion disease [206,207] or from herpes simplex virus type 2 infections [208] with those of hematogenous osteomyelitis, particularly when radiographic findings are considered in context with the characteristic clinical signs and symptoms of these infections.

Numerous noninfectious conditions causing bone destruction or periosteal reaction may be confused with osteomyelitis on clinical and radiographic grounds and on the basis of radionuclide scan findings. These conditions include skeletal trauma caused by the birth process or caregiver abuse [137,209–211] or associated with osteogenesis imperfecta; congenital infantile cortical hyperostosis (Caffey disease) [137,210,212]; congenital bone tumors, metastases, and leukemia [134,197]; extravasation of calcium gluconate at an infusion site [213]; and prostaglandin $E_1$ infusion [214]. The periosteal bone growth sometimes seen in normal infants, particularly premature infants, may produce a "double-contour" effect in long bones that appears to be similar to the early involucrum of healing osteomyelitis, but is unassociated with evidence of bone destruction and metaphyseal changes and is never progressive [215].

## THERAPY

Successful treatment of osteomyelitis or septic arthritis depends on prompt clinical diagnosis and identification of the infectious agent. Every effort should be made to isolate responsible organisms before therapy is initiated. Pus localized in skin, soft tissues, joint, or bone should be aspirated under strict aseptic conditions and sent to the laboratory for Gram stain, culture, and antibiotic susceptibility testing. Blood specimens for culture should be obtained; such cultures may be the only source of the pathogen.* Because osteomyelitis generally is the consequence of a systemic bacteremia, a lumbar puncture should be considered. Any potential source of infection should be examined, including intravascular catheter tips [217]. Cerebrospinal fluid can occasionally be helpful when direct examination of suppurative material fails to

*References [11,31,32,58,119,144].

*References [20,22–24,34–37,75,117,202,203].

†References [20,22,34,37,38,75,203,204].

*References [16,27,35,38,52,55,216].

provide an etiologic diagnosis. Choice of therapy should be guided by results of Gram stain, culture, and antibiotic susceptibilities.

When the cause of infection cannot be immediately determined, the initial choice of antimicrobial agents must be based on the presumptive bacteriologic diagnosis. Penicillinase-resistant penicillins (e.g., nafcillin, oxacillin) and vancomycin are active against *S. aureus*, group A streptococci and GBS, and *S. pneumoniae*, which together account for more than 90% of cases of osteoarthritis in neonates. Osteomyelitis caused by enteric organisms is sufficiently common to justify additional therapy with an aminoglycoside such as gentamicin, tobramycin, or amikacin or an extended-spectrum agent (cefotaxime) or the use of an extended-spectrum, *Pseudomonas*-active agent such as cefepime.

MRSA and most strains of coagulase-negative staphylococci are increasingly frequent causes of sepsis and other focal infections in neonates. Numerous outbreaks of nosocomial and community-acquired MRSA infections have been reported. Infants who acquire infection in nurseries where MRSA is prevalent or where community-acquired MRSA infections have occurred should be started on vancomycin, rather than a penicillin antibiotic [149]. Alternative antibiotics approved and licensed for treatment of MRSA infections in older children and adults, including daptomycin, linezolid, and quinupristin-dalfopristin, have not been fully evaluated or approved for use in neonates in the first 2 months of life and should be employed on an individual basis only when the neonate cannot tolerate vancomycin because of acquired toxicity.

When bacterial culture and sensitivity data are available, treatment should be changed to the single safest and most effective drug. If group B streptococcal infection is confirmed, combination therapy with penicillin G (or ampicillin) and gentamicin should be given for 2 to 5 days, after which time penicillin G (or ampicillin) alone is adequate [218]. Standard disk susceptibility tests may falsely indicate sensitivity of MRSA to cephalosporins [219]. Use of β-lactam antibiotics is inappropriate for MRSA infections, and vancomycin should be continued for the full course of therapy. It is controversial whether the synergistic addition of an active aminoglycoside (e.g., gentamicin) to a penicillin antibiotic or vancomycin for a limited period (e.g., 5 days) enhances the clinical outcomes of infants with neonatal osteomyelitis caused by *S. aureus*.

All antibiotics should be given by the parenteral route, usually intravenously. There is no significant clinical advantage to intravenous over intramuscular administration, but the limited number of injection sites available in the newborn makes the intramuscular route impractical for use during prolonged periods. Intra-articular administration of antibiotics is unnecessary in the treatment of suppurative arthritis because adequate levels of activity have been shown in joint fluid after parenteral doses of most drugs that would be used for therapy [216]. Antibiotic therapy for either osteomyelitis or suppurative arthritis should be continued for at least 4 or 6 weeks after defervescence. Monitoring serum acute-phase proteins (particularly C-reactive protein) has been proposed as a useful way to determine resolution of infection and duration of therapy [110,220,221].

There are insufficient data on the absorption and efficacy of orally administered antibiotics in the neonate to recommend their use routinely in this age group for treatment of osteoarthritis. Nevertheless, after an initial course of intravenous therapy, newborns have been treated successfully with oral dicloxacillin [195,222,223], flucloxacillin [32], fusidic acid [32,33], and penicillin V [32,173] for additional periods ranging from 14 to 42 days. If sequential parenteral-oral therapy is used, adequacy of antibiotic absorption and efficacy must be closely monitored with regular clinical evaluation and, possibly, serum bactericidal titers or, preferably, direct measurement of antibiotic agents in blood [173,223,224]. It is likely, but unproved in the neonate, that the traditional antibiotics used for hematogenous osteomyelitis in older children (e.g., amoxicillin or cephalexin, in divided doses totally 100 to 150 mg/kg/day) would be tolerated and effective, but these agents should be used only after successful parenteral therapy has been established and only under the supervision of physicians with adequate training.

To overcome the uncertainties of oral absorption while still allowing discharge of the patient from the hospital, home intravenous antibiotic therapy has been advocated as an alternative form of treatment [21]. Although home management for older children and adults is now widely accepted, experience with newborns is still limited; however, with proper family and medical support, it can be a successful alternative to inpatient treatment. Either carefully monitored oral therapy or, more frequently, the use of intravenous antibiotics given by peripheral intravenous central catheters or surgically implanted central catheters may be used.

Incision and drainage are indicated whenever there is a significant collection of pus in soft tissues. The need for drilling or "windowing" the cortex to drain intramedullary collections of pus is controversial [11,13,14,32]. There is no evidence, based on controlled studies, that these procedures are of any value in either limiting systemic manifestations or decreasing the extent of bone destruction. Open surgical drainage for relief of intra-articular pressure is a critical measure, however, for preserving the viability of the head of the femur or humerus in infants with suppurative arthritis of hip or shoulder joints [6,35,152]. Intermittent needle aspiration with saline irrigation usually is adequate for drainage of other, more readily accessible joints. Lack of improvement after 3 days, rapid reaccumulation of fluid, or loculation of pus and necrotic debris in the joint may indicate the need for open drainage of these joints as well [225].

The affected extremity should be immobilized until inflammation has subsided, and there is radiologic evidence of healing. Prolonged splinting in a brace or cast is necessary when pathologic dislocation of the head of the femur accompanies pyarthrosis of the hip joint. Maintenance of adequate nutrition and fluid requirements is crucial in determining the ultimate course of the illness. Before the advent of antibiotics, attention to these factors alone often was adequate to ensure prompt healing of osseous lesions in infants who survived the initial septic process [48].

## PRIMARY SEPTIC ARTHRITIS

Although septic arthritis often is a complication of neonatal osteomyelitis, it also can occur in the absence of demonstrable radiologic changes in adjacent bone.

Infection usually is the result of synovial implantation of organisms in the course of a septicemia. Infrequently, traumatic inoculation of organisms into the articular capsule may occur as a consequence of femoral venipuncture [36,59,94–96]. As in osteomyelitis, there is a strong association between septic arthritis and placement of an umbilical catheter [21]. Whatever the source of infection, the presence of a concurrent osteomyelitis can never be ruled out completely because of the possibility that the original suppurative focus lay in the radiolucent cartilaginous portion of the bone, permitting entry of organisms to the joint by direct extension. The spectrum of agents responsible for primary septic arthritis is similar to that of organisms causing arthritis secondary to a contiguous osteomyelitis. Bacteria that have been isolated from blood or joints of newborns in two series are listed in Table 8–2.

Signs and symptoms of purulent arthritis are virtually identical to the signs and symptoms seen in newborns with osteomyelitis [226,227]. Limitation in use of an extremity progressing to pseudoparalysis is characteristic of both conditions, and although external signs of inflammation tend to be more localized to the periarticular area, recognition of this feature is of little diagnostic value in individual cases. Data are insufficient to provide any meaningful comparison between the skeletal distribution of septic arthritis and that of osteomyelitis. Multiple joint involvement is common to both conditions, however. In one series of 16 consecutive newborns with pyarthrosis, 22 joints were involved; 4 (25%) infants had multifocal infections [27]. A migratory polyarthritis, which may precede localization in a single joint by several days, is particularly characteristic of gonococcal arthritis, as is an extremely high frequency of knee and ankle involvement [84]. In a Malaysian series, the knee, hip, and ankle were involved in 10 cases of septic arthritis, and 9 of the 10 cases were caused by MRSA, exhibiting the frequent occurrence of septic arthritis caused by nosocomial pathogens in premature infants in neonatal intensive care units [228].

The radiologic features, differential diagnosis, and therapy for septic arthritis are discussed in "Osteomyelitis." Studies of long-term evaluations are rare, precluding an accurate assessment of the prognosis for this condition.

**TABLE 8–2** Reported Spectrum and Organisms Isolated from Blood or Joints of Neonates with Primary Bacterial Arthritis (1972-1986)

| Bacteria | No. Infants |
|---|---|
| *Staphylococcus aureus* | 9 |
| Group B *Streptococci* | 4 |
| *Streptococci*, unspecified | 2 |
| *Staphylococcus epidermidis* | 1 |
| *Haemophilus influenzae* type b | 0 |
| *Escherichia coli* | 0 |
| *Klebsiella pneumoniae* | 1 |
| *Pseudomonas aeruginosa* | 1 |
| *Neisseria gonorrhoeae* | 1 |

## OSTEOMYELITIS OF THE MAXILLA

Neonatal osteomyelitis of the maxilla is a distinct clinical entity, and early reports of neonatal osteomyelitis frequently focused exclusively on this entity. In terms of total numbers, maxillary osteomyelitis is a rare condition (there are <200 reported cases); yet in earlier surveys of neonatal bone infections, maxillary involvement was noted in approximately 25% of infants.* The far lower incidence in children [8,10] and adults [150] is probably explained by earlier recognition and treatment of sinusitis in these age groups and by the lack of predisposing factors unique to the newborn.

The causative organism is most frequently *S. aureus* [230–232], although hemolytic streptococci have been isolated on rare occasions from drainage sites [232]. More than 85% of all maxillary infections in infants occur in the first 3 months of life; the incidence is highest during the 2nd to 4th weeks [231–234].

In most cases, the predisposing cause remains obscure. Infants with sources of infection, such as skin abscesses or omphalitis, constitute a small minority [232,233]. It has been postulated that there is a relationship between breast abscess in the nursing mother and maxillary osteomyelitis [232,233,235]; however, it is unclear whether the maternal infection is a source or a result of the infant's condition [236]. The pathogenesis of bone infection after colonization of the infant by staphylococci is equally uncertain. In some cases, osteomyelitis is believed to result from extension from a contiguous focus of infection in the maxillary antrum. Alternatively, organisms may be blood-borne, establishing infection in the rich vascular plexus surrounding tooth buds [234]. Although the hematogenous route may be important in certain cases, particularly cases involving the premaxilla [230], this explanation is incompatible with the fact that mandibular osteomyelitis or associated metastatic involvement of other structures is uncommon [232]. Another theory is that trauma or abrasion of the gum overlying the first molar is the primary route of introduction of organisms [233].

The clinical course of maxillary osteomyelitis begins with acute onset of fever and nonspecific systemic symptoms. Shortly thereafter, redness and swelling of the eyelid appear and are frequently accompanied by conjunctivitis with a purulent discharge. Thrombosis of nutrient vessels and increasing edema may cause a proptosis or chemosis of the affected eye. In most infants, an early and diffuse swelling and inflammation of the cheek may localize to form an abscess or draining fistula below the inner or outer canthus of the eye; this is nearly always followed or accompanied by a purulent unilateral nasal discharge that is increased by pressure on the abscess. The alveolar border of the superior maxilla on the affected side is swollen and soft, as is the adjacent hard palate. Within a few days, abscesses and draining fistulas may form in these areas [237]. Sepsis and death are frequent in untreated cases. In most infants, the illness pursues a relatively chronic course characterized by discharge of premature teeth or numerous small sequestra of necrotic bone through multiple palatal and alveolar sinuses that have formed. The entire course may evolve over several days in severe cases, or it may extend for several weeks in mild or partially treated cases.

*References [3,6,11,48,55,229].

Neonatal maxillary osteomyelitis is frequently confused with either orbital cellulitis or dacryocystitis [13,233,238]. The early edema and redness of the cheeks that accompany acute osteomyelitis constitute an important differentiating feature, which is not observed in orbital cellulitis and occurs only as a late sign in infection of the lacrimal sac. Neither orbital cellulitis nor lacrimal sac infection is associated with a unilateral purulent nasal discharge. The early onset, limited area of involvement, and Gram stain characteristic of ophthalmia neonatorum should be sufficient, in most cases, to permit diagnosis of this condition. CT can be helpful in assessing the extent of infection and evaluating for possible complications, such as cerebral abscess [237].

Therapy for maxillary osteomyelitis should be directed toward early adequate drainage of the maxillary empyema and contiguous abscess and should include appropriate parenterally administered antibiotics. Because most infections are due to *S. aureus* and group A streptococci, systemic use of a penicillinase-resistant penicillin (or vancomycin) alone should be sufficient as initial therapy pending the results of bacterial cultures and sensitivity tests. The need for or desirability of instillation of antibiotics into the maxillary antrum is uncertain.

Before the advent of penicillin therapy, the mortality rate for maxillary osteomyelitis was high, ranging from 15% to 75% in various series [232,233,235,239]. Children who survived often had severe facial and dental deformities. Later studies [232,233,239] showed a mortality rate of closer to 5%, although sequelae such as stenosis of the lacrimal duct, ectropion, permanent loss of teeth, malocclusion, and facial hemiatrophy are still seen [11,231–233]. In many instances, these complications could have been prevented through early recognition of the nature of the illness and prompt institution of appropriate therapy.

CHAPTER 9

# Bacterial Infections of the Urinary Tract

**Sarah S. Long** ✪ **Jerome O. Klein**

## CHAPTER OUTLINE

In 1918, Helmholz [1] recognized the cryptogenic nature and underdiagnosis of urinary tract infection (UTI) in the newborn. His observations still hold true today. There are no specific signs of UTI in a newborn; the clinical presentation can vary, ranging from fever with or without other signs of septicemia to minimal changes such as alteration in feeding habits or poor weight gain. The diagnosis of UTI in a neonate is made only by the examination and culture of a properly obtained specimen of urine.

The reported incidence, clinical manifestations, and prognosis of UTI in neonates have varied significantly. There are at least two reasons for discrepant results obtained in studies of UTI: (1) Different criteria have been used to define UTI, and (2) infants with different characteristics have been studied. Before 1960, clean-voided specimens were used almost exclusively for examination and culture of urine. It is now clear that contamination is frequent when this method is used; Schlager and coworkers [2] observed that 16 cultures of urine obtained by bag collection from 98 healthy newborns yielded greater than $10^4$ colonies per milliliter of urine, with organisms that were found also on periurethral skin. The only reliable methods for obtaining urine for bacteriologic study are percutaneous aspiration and urethral catheterization of bladder urine.

Bacterial infections of the kidney and urinary tract in neonates usually are acquired at or after delivery. Fungal infections develop as nosocomial infections in infants with risk factors such as prematurity and use of intravascular catheters, parenteral alimentation, and broad-spectrum antibiotics or after prolonged or intermittent catheterization of the urinary tract [3,4]. Viral infections, including rubella, herpes simplex, and cytomegalovirus infections, are responsible for in utero infection, although the organisms can be excreted in the urine for months after birth. Bacterial infections of the urinary tract (other than those related to *Neisseria gonorrhoeae*, *Staphylococcus aureus*, and group B streptococci) are reviewed here. For information about infection and disease of the kidney and urinary tract caused by other microorganisms, the reader is referred to the chapters on toxoplasmosis, rubella, cytomegalovirus, herpes simplex, syphilis, the mycoplasmas, *Candida*, group B streptococci, gonorrhea, staphylococcal infection, and neonatal diarrhea (*Salmonella*).

## EPIDEMIOLOGY

The incidence of UTI in infants in the first month of life varies, ranging from 0.1% to 1% in older studies [5–11]. Using a national database for 2003, rate of hospitalization for UTI was 53.6/100,000 population younger than 1 month of age [12]. Frequency may be 10% in infants of low birth weight [13] and 12% to 25% in infants of very low birth weight evaluated for sepsis (Table 9–1) [14,15]. In contrast to the increased incidence of bacteriuria among females in other age groups, infection of the urinary tract in the first 3 months of life is more frequent in males [2,5–10,15,17].

Infection of the urinary tract is usually sporadic, but clusters of cases, closely related in time, have been reported from nurseries in Cleveland [18] and Baltimore [19]. A nursery epidemic caused by *Serratia marcescens* was responsible for UTI and balanitis. The outbreak was caused by contamination of a solution applied to the umbilical cord [20].

Surveys of infants born in U.S. Army medical centers and subsequently hospitalized for UTI indicate that uncircumcised boys have more UTIs than circumcised boys in the first month and in months 2 to 12 of life (Table 9–2) [11,21,22]. In 1982, Ginsburg and McCracken [23] observed that 95% of 62 infant boys with UTI were uncircumcised. A case-control study performed in 112 infant boys in whom suprapubic aspiration or bladder catheterization had been performed for investigation of acute illness showed that all infants with UTI were uncircumcised compared with 32% of controls [24]. Infection was associated with anatomic abnormalities in 26% of cases. In a meta-analysis of infants younger than 3 months who were evaluated for fever, rates of UTI were 7.5% for girls, 2.4% for circumcised boys, and 20.1% for uncircumcised boys [25]. The records of more than 136,000 boys born in U.S. Army hospitals from 1980-1985 were reviewed through the first month of life to compare clinical courses in uncircumcised and circumcised boys [26]. Of 35,929 uncircumcised boys, 88 (0.24%) had UTI, 33 had concomitant bacteremia, 3 had meningitis, 2 had renal failure, and 2 died. Complications followed 0.19% of 100,157 circumcisions (including 20 UTIs), and all were minor except for three episodes of hemorrhage leading to transfusion. Meta-analysis of nine published studies through 1992 yielded an overall 12-fold increased risk of infection in uncircumcised boys [27].

In 1989, the American Academy of Pediatrics (AAP) rescinded a 1971 position against circumcision, recognizing the relative safety of the procedure and protection against UTI in the first year of life [28]. More recent studies using case-control and cohort design also support an association, with threefold to sevenfold magnitude of risk for uncircumcised boys [29,30]. In 1999, the AAP revised the recommendation, citing that although existing scientific evidence shows potential medical benefits of newborn male circumcision, data are insufficient to recommend its routine performance [31].

Ritual Jewish circumcision performed on the 8th day of life, when periurethral bacterial colonization has been established, seems to have attendant risk for UTI. An epidemiologic study in Israel revealed excessive UTIs in boys only from days 9 to 20 of life (the postcircumcision period) [32]. A case-control study identified performance by a nonphysician (mohel) versus a physician as a risk factor for UTI (odds ratio 4.34); the authors postulate technique of hemostasis and duration of the shaft wrapping as responsible factors [33].

## MICROBIOLOGY

*Escherichia coli* continues to be responsible for most community-acquired infections of the urinary tract in infants younger than 3 months, accounting for 90% or more cases reported through the 1990s [34–36], with lower prevalence since, possibly related to widespread use of intrapartum chemoprophylaxis [4,37]. Many O serotypes of *E. coli* have been associated with UTI. UTI in neonates was associated with a limited number of O:K:H serotypes with P fimbriae, adhesive capacity, hemolysin production, and serum resistance [38,39]. The serotypes of *E. coli* associated with diarrhea rarely cause UTI, however. Cultures of urine can be positive in infants with septicemia caused by group B streptococci, but primary infection of the urinary tract without septicemia is uncommon [17,40]. Community-associated UTI in neonates with or without bloodstream infection has been reported caused by *Staphylococcus aureus* [37,41].

The incidence of neonatal UTI as a complication of intensive care has increased sharply in recent years; intensive care–associated UTI occurs in patients with and without urinary catheters [3]. Microbiology of neonatal nosocomial UTI is dramatically different from that observed in neonatal intensive care units in the 1970s (Table 9–3), with *E. coli* supplanted by other Enterobacteriaceae genera, *Pseudomonas*, *Enterococcus*, *Candida*, and coagulase-negative staphylococci [3,4,14,15,42–44]. Multiple pathogens may be present; Maherzi and colleagues [9] identified more than one bacterial pathogen in 4 of 43 infants with UTI documented by aspiration of bladder urine.

*S. aureus* and *E. coli* have been responsible for localized suppurative disease of the urinary tract in neonates, including prostatitis, orchitis, and epididymitis [45–49]. Other examples of focal disease in the urinary tract include orchitis caused by *Pseudomonas aeruginosa* [50] and testicular abscess caused by *Salmonella enteritidis* [51]. Blood cultures frequently are positive in affected infants. Bacteria responsible for infections of the circumcision site are discussed in “Infections of the Skin and Subcutaneous Tissue” in Chapter 10.

## PATHOGENESIS

In older children and adults, most UTIs are thought to occur by the ascending route after introduction of bacteria through the urethral meatus. Less frequently, blood-borne infection of the kidney occurs. In neonates, it is frequently difficult to know whether UTI was the cause or the result of bacteremia. The predominance of males among infants younger than 3 months with UTI contrasts with the predominance of females in all other age groups. This difference may reflect increased risk of UTI in young uncircumcised boys; increased prevalence of urinary and renal anomalies in boys; transient

urodynamic dysfunction; vesicoureteral reflux (VUR), which predominantly affects male infants; and the occasional UTI that complicates circumcision. Additionally, bacteremia is more frequent in male infants, and it is likely that hematogenous invasion of the kidney can cause UTI in neonates.

Anatomic or physiologic abnormalities of the urinary tract play a role in the development and consequences of infection in some infants. Obstructive uropathy is the most important. Infection often is the first indication of an abnormality. Infection was the presenting sign in half of 40 infants younger than 2 months of age with anomalies of the kidneys or ureters reported in 1980 [52]. Congenital obstruction of the urinary tract was diagnosed in 5 of 80 children with UTI studied in Göteborg [6] and in 2 of 60 children studied in Leeds [53]; important radiologic abnormalities of the urinary tract were identified in 10 of 46 infant boys and 3 of 13 infant girls younger than 3 months from 1972-1982 in Christchurch, New Zealand [54]. Increasingly, antenatal ultrasonography identifies fetuses with significant anatomic abnormalities, and early neonatal intervention (with prophylactic use of antibiotics or surgery or both) may decrease likelihood of infection.

VUR is identified in many infants with UTI who are examined by radiologic techniques. It is frequently the result of infection, but also can be a primary defect. VUR is not a prerequisite for upper tract infection (i.e., pyelonephritis); in two studies, less than half of children with pyelonephritis by scintigraphy had VUR [55,56]. Majd and coworkers [57] found that 23 of 29 (79%) children hospitalized for UTI who were found to have reflux had pyelonephritis by scintigraphy; 39 of 65 (60%) children without reflux also were found to have pyelonephritis. VUR can be a congenital abnormality. Fetal ultrasonography showed that 30 of 107 infants with prenatally diagnosed urinary tract abnormalities had reflux, which was the only abnormality found postnatally in 10 infants [58]. Gordon and colleagues [59] observed that 16 of 25 infants with dilation of the fetal urinary tract had reflux, which was of grade 3 to 5 severity in 79%. In Austrian infants, 39 urinary tract abnormalities detected prenatally were compared with 46 urinary tract abnormalities found after first UTI [60]. Obstructive lesions and multicystic dysplastic malformations of the kidneys accounted for 90% of all prenatally diagnosed malformations, and reflux accounted for only 10%. By contrast, reflux accounted for 59% of abnormalities detected after the first UTI.

VUR detected prenatally has a male-to-female distribution of 6:1 (in contrast to VUR detected after UTI, when females predominate) [61], may be determined developmentally by the site of the origin of the ureteral bud from the wolffian duct, and in severe cases can be associated with congenital renal damage consisting of global parenchymal loss (so-called reflux nephropathy) [62]. Gunn and colleagues [63] performed ultrasound examinations of 3228 fetuses; no renal tract abnormalities were detected before 28 weeks of gestation. Subsequently, 3856 fetuses were examined by ultrasonography after

28 weeks of gestation. Urinary tract anomalies were identified in 313 fetuses; 15 had major structural abnormalities, all of which were confirmed postnatally. In 298 (7.7%) of the fetuses, dilated renal pelvis with normal bladder was found; most of the cases resolved spontaneously, but 40 of the cases were confirmed postnatally to be due to serious abnormalities (usually obstruction or VUR) [64]. In one study, preterm infants with nosocomial UTI had a lower incidence of VUR than that noted in term infants with nosocomial UTI [15]; however, in another study comparing 250 neonates (mean gestation age 39 weeks) with community-associated UTI with 51 neonates (mean gestation age 36 weeks) with nosocomial UTI, the neonates with nosocomial infection were more likely to have VUR and abnormal renal ultrasound examination [4].

Isolated mild renal pyelectasis (i.e., <10 mm diameter of the collecting duct and without VUR) in fetuses is likely to be transient, unassociated with pathology or risk for UTI [65,66]. In one study, 54% of such cases had resolved in the first postnatal month, and 85% of the cases of moderate or severe pelviectasis had resolved or improved over the first 2 years of life [67]. In a long-term study performed in the United Kingdom of 425 infants with antenatally detected hydronephrosis, 284 had normal findings on neonatal ultrasound examination; negative predictive value of normal ultrasound findings for subsequent UTI in the first year of life was 99% [68].

In a more recent 5-year retrospective statewide, cohort analysis of 522 Washington infants with birth-hospital discharge diagnosis of antenatal hydronephrosis (not quantified further) and 2610 control infants, hospitalization for UTI in the first year of life was 5% versus 1% (relative risk 11.8, 95% confidence interval 6.8 to 20.5). Relative risk for UTI was higher especially among girls with antenatal hydronephrosis (relative risk 36.3, 95% confidence interval 10.6 to 124.0) [69]. In a 17-year study from a single institution in Seoul of 480 infants with antenatal and postnatal hydronephrosis without VUR, UTI developed in the first year of life in 39% of infants with obstructive uropathy compared with 11% without obstructive uropathy ($P < .001$). Higher grade of hydronephrosis and presence of hydroureteronephrosis were associated with higher incidence of UTI [70].

Results of a long-term outcome study of 125 infants in the Netherlands with antenatal hydronephrosis suggested that a cutoff of less than 15 mm anterior-posterior diameter of the renal pelvis identified infants at low risk for UTI or surgical conditions and low incidence and benign course of VUR [71]. In a long-term study in Toronto of 260 infants with a diagnosis of prenatal hydronephrosis, 25 also had VUR (grade 3 or higher in 73%), received antibiotic prophylaxis, and did not have surgical correction during 4 years of follow-up. Breakthrough infection occurred in only four patients. Improvement was seen in most of the children with VUR, and there was no difference in renal growth in children who had resolved versus unresolved VUR or high-grade versus low-grade VUR [72]. Postnatal management of prenatal hydronephrosis is controversial. Many experts favor evaluation of even mild cases by postnatal ultrasonography and voiding cystourethrography [73].

The outcome of interest for strategies to identify obstructive uropathy, hydronephrosis, VUR, and UTI is to attempt to lessen renal damage. Except for obstructive uropathies, the relative impacts and benefits of special management of hydronephrosis and VUR are increasingly controversial. A National Institutes of Health multicenter, randomized, placebo-controlled, double-blind study has been designed to determine preventive effect of antimicrobial prophylaxis on recurrent UTI and renal scarring in children with primary VUR (i.e., not due to increased bladder pressure as from a neurogenic bladder, outlet obstruction, or other vesicular anomalies) [74]. Chesney and colleagues [75] commented on background knowledge and rationale for the study design. A few relevant points are as follows: (1) The percentage of patients with recurrent UTIs and VUR who develop renal scarring is small. (2) Many children, even those with high-grade VUR, do not develop scars. (3) Patients without VUR who have recurrent UTI can develop scars. (4) Older studies (with poorer outcomes) included patients with secondary VUR (i.e., high-pressure VUR) and genetic renal syndromes. (5) Trials of antimicrobial prophylaxis or surgery or both for VUR generally are underpowered and do not include a nonintervention arm. (6) In a Cochrane analysis using 10 trials involving 964 children, authors could not conclude that identification and treatment of children with VUR conferred a long-term benefit.

In a multicenter, randomized controlled follow-up trial of antimicrobial prophylaxis compared with no prophylaxis in 100 Italian infants with grades II through IV VUR, prophylaxis had no effect on recurrences of UTI, renal scarring, or persistence of VUR. Recurrences in the prophylaxis group were caused by multidrug-resistant bacteria, whereas recurrences in the group not receiving prophylaxis all were due to antibiotic-susceptible *E. coli* [76].

Bacterial virulence factors are likely to play an important role in the pathogenesis of UTIs. Strains of *E. coli* causing UTI are a selected sample of the fecal flora. Pyelonephritic isolates belong to a restricted number of serotypes, are resistant to the bactericidal effect of serum, attach to uroepithelial cells, and produce hemolysins [77]. Pili on the bacterial cell surface that adhere to specific receptors on epithelial cells may play a role in development of UTI [38]. Some of these features of pyelonephritic strains of *E. coli* have been shown in UTIs in newborns [38,39].

The increased rate of UTIs in uncircumcised boys is likely to be associated with periurethral bacterial flora. During the first 6 months of life, uncircumcised boys have significantly higher total urethral bacterial colony counts and more frequent isolation and higher colony counts of uropathogenic organisms such as *E. coli*, *Klebsiella-Enterobacter* species, *Proteus*, and *Pseudomonas* [78]. With increasing age, the foreskin is more easily retracted, and penile hygiene improves; by 12 months of age, the excessive periurethral flora and UTIs in uncircumcised boys almost disappear [22,78].

Natural defenses in the urinary tract include antibacterial properties of urine, antiadherence mechanisms, mechanical effects of urinary flow and micturition, presence of

phagocytic cells, antibacterial properties of the urinary tract mucosa, and immune mechanisms [79]. There is scant knowledge about these mechanisms in the newborn.

## PATHOLOGY

The histologic appearance of acute pyelonephritis in newborns is similar to that in the adult [80]. Polymorphonuclear leukocytes are present in the glomeruli, the tubules, and the interstitial tissues. The renal pelvis can show signs of acute inflammation, with loss of the lining epithelium and necrosis. Focal suppuration can be present in the kidney, prostate, or testis. In disease of longer duration, the interstitial tissue is infiltrated with lymphocytes, plasma cells, and eosinophils. The number of glomeruli may be decreased, and some may be hyalinized. The epithelium of tubules is atrophic, and the lumen is filled with colloid casts. Pericapsular fibrosis is present in some infants. If the infant dies within 6 months, there is little scarring or contraction of the kidney. Reversible hydronephrosis and hydroureter are observed manifestations of acute pyelonephritis in the neonate who has no anatomic abnormality or VUR. It is postulated that bacteria and endotoxins inhibit ureteral peristalsis.

Pathologic processes indicative of additional suppurative infections, such as otitis media, pneumonia, and meningitis, also can be seen in infants dying of acute infection of the urinary tract. Hepatocellular damage and bile stasis may be noted in liver sections from jaundiced infants [81].

## CLINICAL MANIFESTATIONS

The signs of UTI in neonates are varied and nonspecific. Five patterns are generally observed: (1) septicemia associated with early-onset (within the first 5 days of life) or late-onset (after 5 days of age) disease (see Chapter 21); (2) acute onset of fever without apparent source; (3) insidious illness marked by low-grade fever or failure to gain weight; (4) no apparent signs; and (5) localized signs of infection, including balanitis, prostatitis, urethritis, and orchitis.

The most frequent signs of acute UTI are associated with fever or septicemia or both (see Chapter 21) (Table 9–4) [4–6,8,9]. Less acute and nonspecific manifestations also are common, and the presenting signs include

**TABLE 9–4** Clinical Manifestations of Urinary Tract Infections in Newborn Infants

| Clinical Manifestations | % of Infants with Manifestations* |
|---|---|
| Fever | 55 |
| Vomiting | 27 |
| Failure to thrive | 26 |
| Poor feeding | 24 |
| Irritability or lethargy | 17 |
| Jaundice | 10 |
| Diarrhea | 8 |

**When sign was not mentioned in report, the number of infants in the report was removed from the denominator used to determine the percentage of infants with manifestations.*
*Data from references [4–6], [8], [9].*

poor weight gain, vomiting, and poor feeding. Fever was a less common feature of nosocomial UTI in one study compared with community-associated cases [4]. Enlargement of the liver and spleen and distention of the abdomen can be present. The kidneys may be enlarged or abnormal in shape or position, and anomalies of the urethra and penis also can occur. Signs associated with renal anomalies (e.g., a single umbilical artery, supernumerary nipples, spina bifida, low-set ears, and anorectal abnormalities) are seen in some infants.

Jaundice is an important feature of UTI and can be the presenting sign [81,82]; it is frequently sudden in onset and clears rapidly after adequate antimicrobial therapy. Many infants with UTI and jaundice have positive blood cultures [19,82]. Of 306 infants in one study admitted to the hospital within 21 days of birth solely because of indirect hyperbilirubinemia (mean peak serum bilirubin level 18.5 mg/dL), 90% were breast-fed, and none had a positive culture of urine or blood [83]. In another study, 12 of 160 (7.5%) infants younger than 8 weeks of age evaluated solely for jaundice had UTI confirmed by bladder catheterization, however. Renal ultrasound was abnormal in 6 of 11 infants. Infection was especially associated with elevated conjugated bilirubin and age of more than 8 days [84]. In a study of 100 infants whose sole abnormality was jaundice lasting beyond 2 weeks of age, all were breast-fed, and 6 had UTI [85].

A reported case of severe methemoglobinemia observed in a 3-week-old infant with *E. coli* UTI was postulated to be caused by nitrite-forming bacteria, but concurrent diarrhea, dehydration, and acidosis may have been precipitating factors [86]. Hyperammonemic encephalopathy caused by *Proteus* infection in children with urinary tract obstruction or atony also has been described [87]. Bacteriuria without apparent signs of illness also was documented occasionally in screening studies performed in the 1970s and 1980s [5,7,10,13].

Abscesses of the prostate, testis, or epididymis usually manifest as signs of septicemia, including fever, vomiting, and diarrhea [45–51]. Local signs of inflammation, including tenderness and swelling over the surface of the infected organ, may be present. Urinary retention occurs in infants with prostatitis [47]. Renal abscess is rare in neonates; at least one case report in a neonate (with congenital nephrosis) has been published [88].

UTI should be considered in the differential diagnosis for unexplained fever in early infancy. UTI with or without bacteremia is the most common cause of serious bacterial infection in infants younger than 3 months evaluated because of fever; it was responsible for 79% of cases in a Utah study [37]. Presence of UTI has been studied in thousands of infants younger than 3 months who have been evaluated because of fever by practitioners in emergency department and office settings. Rates range from 5% to 13%, depending predominantly on prevalence of circumcision in the population [89–94]. In a New York study, prevalence of UTI in febrile infant boys (82% of whom were not circumcised) was 12.4%. In a Pittsburgh study, prevalence of UTI in febrile infant boys (2% of whom were not circumcised) was only 2.9%. In a multicenter prospective study of febrile infants younger than 2 months, 9% had UTI (21% of uncircumcised boys, 5% of girls, and 2% of

circumcised boys) [95]. In a study of 162 febrile Japanese infants younger than 8 weeks, 22 (13.8%) had UTI; 18 were boys, none of whom was circumcised [96].

In a study of 2411 febrile children younger than 24 months evaluated in an emergency department in Philadelphia, history of malodorous urine, prior history of UTI, and presence of abdominal tenderness were significantly associated with the diagnosis of UTI; findings were present in less than 10% of infected infants, however, and only 8% to 13% of infants with findings had UTI confirmed [36]. In a retrospective study of 354 Boston infants younger than 24 months with confirmed UTI, irritability and decreased appetite were each reported in 50% of children; diarrhea, vomiting, lethargy, and congestion were reported in 25%; and malodorous urine, apparent dysuria, frequency of urination, and abdominal pain were reported in less than 10% [17].

## DIAGNOSIS

Infection of the urinary tract is defined as the presence of bacteria in urine that was obtained without contamination from the urethra or external genitalia. UTI should be considered in all infants older than 3 days of age who have fever or other signs of septicemia or who have subtle and nonspecific signs of failure to thrive during the first months of life. At present, no clinical finding or simple laboratory test adequately defines the location of infection in the urinary tract of the infant. It is assumed that bacteriuria in the neonate indicates infection throughout the urinary tract (including the kidney).

### CULTURE OF URINE

Suprapubic needle aspiration of bladder urine is the most reliable technique for identifying bacteriuria. Although a negative result from culture of bag-collected urine indicates that the urine is sterile, 12% to 21% of bag-collected specimens yield results that are indeterminate or positive (colony count $\geq 10^4$/mL) [2,34], and positive results must be verified by aspiration of bladder urine or by catheterization. There is frequently insufficient time for this stepwise approach before institution of therapy. The technique of needle aspiration of the bladder has been used extensively, is technically simple and safe, and causes minimal discomfort to the infant [97]. Although most infected infants have urine specimens with bacterial colony counts of $10^5$/mL or greater, any bacterial growth in urine obtained by suprapubic aspiration is significant.

Morbidity associated with suprapubic aspiration is minimal. Transient gross hematuria has been reported in 0.6% of 654 infants [97]. Gross bleeding that ceased only after cauterization was reported in one case [98]. Perforation of the bowel occurred in two cases, but this complication is avoided if the bladder is defined by palpation or percussion [98]. Hematoma of the anterior wall of the bladder [99], peritonitis [100], and anaerobic bacteremia [101] also have been reported after suprapubic aspiration. These reports warranted publication because the cases are very uncommon. The possibility of these complications should not deter the physician from using this technique for infants with suggested septicemia. Suprapubic aspiration should not be performed, however, if the infant has recently voided, has abdominal distention, has poorly defined anomalies of the urinary tract, or has a hematologic abnormality that might result in hemorrhage.

Suprapubic aspiration of bladder urine should be performed at least 1 hour after the patient has voided. The infant should lie supine, with the lower extremities held in a frog-leg position. The suprapubic area is cleaned with iodine and alcohol. A 20-gauge, 1½-inch needle attached to a syringe is used to pierce the abdominal wall and bladder approximately 1 inch above the symphysis pubis. The needle is directed caudally toward the fundus of the bladder, and urine is aspirated gently. Vigorous aspiration should be avoided because the mucosa can be drawn in to block the needle opening. The aspirated urine is sent to the laboratory immediately in a sterile tube. If the infant urinates during the procedure, or if the procedure cannot be done properly for other reasons, aspiration should be repeated after 1 to 2 hours. Ultrasound examination may be useful in detecting the presence of urine in the bladder before suprapubic aspiration; with ultrasound-guided aspiration, the success rate for acquisition of an adequate sample of urine improved from 60% to 96.4% [102].

Catheterization of the bladder using sterile technique also is an appropriate sampling method. The incidence of infection related to catheterization in infants is unknown. Urine for culture should be transported to the laboratory as soon as possible, but if a delay is unavoidable, the specimen must be refrigerated. Isolation of $10^3$ colonies/mL or greater of urine obtained by catheter may represent significant bacteriuria in this age group [103]. In multiple studies of young children evaluated because of fever (relatively few of whom were neonates), approximately 80% of the children with bacteriuria had colony counts of $10^5$/mL or greater. Significant pyuria, elevated serum level of C-reactive protein (CRP), isolation of a single enteric organism, and abnormality on renal scintigraphy were each decreasingly associated with lower colony counts, with only rare positive tests in children with colony counts of less than $10^4$/mL [16,17,35,104].

### CULTURE OF BLOOD AND CEREBROSPINAL FLUID

Because bacteremia and meningitis can accompany UTI, cultures of the blood and cerebrospinal fluid should be obtained before therapy for UTI is begun if the neonate has fever or any signs of illness. Blood (but not cerebrospinal fluid) for culture also should be obtained from a neonate with UTI, but without specific or nonspecific signs of infection. In a study from Sweden in the 1970s [6], lumbar puncture was performed before therapy in 31 neonates with UTI; 6 infants had purulent meningitis, and in 9 infants the cerebrospinal fluid was sterile but pleocytosis (22 to 200 white blood cells [WBCs]/mm$^3$) also was present. Blood was obtained for culture in 32 infants and was positive in 12 infants. Meningitis accompanied UTI in less than 2% of young Australian infants reported in 2007 [105]. Although sterile cerebrospinal fluid pleocytosis has been reported in association with UTI in young infants, a 2008 report of a multicenter prospective study of 1025 febrile infants younger than 2 months, in which 91 had

confirmed UTI, sterile cerebrospinal fluid pleocytosis was uncommon—found in 0% to 8% depending on the definition of pleocytosis. Overinterpretation of pleocytosis resulting from traumatic lumbar puncture may be the explanation for the previously reported association [106].

Bacteremia was present in 11 of 35 (31%) Dallas infants younger than 30 days of age with UTI. The infants had been considered healthy when discharged from the nursery and were evaluated because of fever. Older infants with UTI were less likely to be bacteremic; positive cultures of blood occurred in 5 of 24 infants (21%) with UTI 1 to 2 months of age, 2 of 14 infants (14%) 2 to 3 months of age, and 1 of 18 infants (5.5%) 3 months of age or older [23]. Similarly, in Boston, bacteremia was present in 17 of 80 (21%) febrile infants with UTI younger than 1 month of age, 8 of 59 (13%) 1 to 2 months of age, and 8 of 116 (7%) 2 to 6 months of age; 4 neonates had meningitis [17]. In Pittsburgh, incidence of bacteremia in community-associated UTI was higher in infants younger than 2 months (22%) than in older infants (3%) [107]. No clinical finding or laboratory test discriminated between bacteremic and nonbacteremic infants [17]. In surveillance for UTI among 203,399 infants born in U.S. Army hospitals from 1985-1990, 23% of noncircumcised infant boys younger than 3 months with UTI had concomitant bacteremia; incidence of bacteremia associated with UTI was not different from the incidence in circumcised boys or girls with UTI [27]. Incidence of bacteremia in neonatal nosocomial UTI is higher than in community-associated infection; bacteremia occurred in 38% of cases of nosocomial UTI in one study [14].

## EXAMINATION OF URINE SEDIMENT

Many studies and a meta-analysis assessing presence of WBCs in the urine of newborn infants have been performed [5,22,70,108–111]. Healthy infants can have 10 WBCs/$mm^3$ of clean-voided urine [109]. Lincoln and Winberg [110] obtained clean-voided specimens of urine from uninfected infants younger than 1 week of age; boys had up to 25 WBCs/$mm^3$, and girls had up to 50 WBCs/$mm^3$.

Neither presence nor absence of pyuria is completely reliable evidence for or against UTI. Many studies have assessed urine specimens for predictive values for UTI of WBCs or organisms or detection by dipstick of leukocyte esterase or reduction of nitrate. The following results are limited to studies of acutely ill, usually febrile infants whose urine was obtained by catheterization (or suprapubic aspiration where stated). Methods of assessing pyuria and definitions of UTI vary. In 27% of unspun urine samples collected by suprapubic aspiration from Dallas infants with UTI (bacterial colony counts $\geq 10^5$/mL), less than 10 WBCs per high-power field were present [23]. Landau and coworkers [16] reported that among infants younger than 4 months with positive urine cultures (colony counts $\geq 10^4$/mL), 4 of 49 (8.2%) with acute pyelonephritis diagnosed on renal scintigraphy had less than 5 WBCs per high-power field (400×) in fresh centrifuged urine compared with 27 of 79 (34.2%) infants with UTI and negative results on scintigraphy.

Quantifying WBCs in uncentrifuged urine using a counting chamber is the most reproducible test for pyuria. Hoberman and colleagues [112] found pyuria (at least 10 WBCs/$mm^3$ of unspun urine) absent in 22 of 190 (20%) febrile infants younger than 24 months with positive urine cultures (colony counts $\geq 5 \times 10^4$/mL) and present in 6.7% with negative cultures; a single patient of 15 cases without pyuria in whom renal scintigraphy was performed under protocol had a positive result. In a study by Hansson and coworkers of 366 infants younger than 1 year with symptomatic UTI (colony counts $\geq 10^3$/mL from suprapubic aspirate of urine), 80% had colony counts of $10^5$/mL or greater, 13% had counts of $1 \times 10^4$ to $9 \times 10^4$/mL, and 7% had counts of $1 \times 10^3$ to $9 \times 10^3$/mL. Pyuria was significantly associated with colony count. In children with UTI with colony counts of less than $10^5$/mL, sensitivity of pyuria (>10 WBCs/$mm^3$) was 69% compared with 88% for children with at least $10^5$ colonies/mL. Nitrate reduction test was highly insensitive; 44% of the patients had a positive result when the colony count was at least $10^5$/mL, and 11% had a positive result with lower counts [35]. Nitrate reduction would be expected to be negative in all cases in which non-Enterobacteriaceae, gram-positive cocci or *Candida* are causative. Renal scintigraphy was not performed in the study by Hansson and coworkers to estimate significance of UTI, but VUR was present equally in infants with high (30%) and low (38%) colony counts.

Dipstick test for leukocyte esterase and nitrite is inadequate to exclude the diagnosis of UTI in infants. In the study by Hoberman and colleagues [104], the test had a sensitivity of 53% and positive predictive value of 82% for detecting 10 or more WBCs/$mm^3$; nitrite determination had a sensitivity of 31% in identifying urine cultures with growth of at least 50,000 colonies/mL. Shaw and coworkers [113] reported dipstick results in 3873 febrile children younger than 2 years evaluated for UTI; sensitivity of a positive result (trace or greater for leukocyte esterase or positive nitrite) was 79%, and positive predictive value was 46% for isolation of at least 10,000 colonies/mL from urine culture.

Microscopic hematuria is present in some infants with UTI [3,44]. Gross hematuria usually is associated with other diseases (e.g., renal vein thrombosis, polycystic disease of the kidney, obstructive uropathy, Wilms tumor) [114].

Usefulness of Gram stain of urine specimens in predicting bacteriuria has been studied prospectively in febrile infants younger than 24 months. Smears were prepared using 2 drops of uncentrifuged urine on a slide within a standardized marked area 1.5 cm in diameter, which was then air dried, fixed, and stained. The presence of at least one organism per 10 high-power fields examined using oil immersion lens was considered a positive result. Sensitivity and positive predictive value were 81% and 43% for isolation of at least $1 \times 10^4$ colonies/mL of urine in Shaw and colleagues' study [113] and 93% and 57% for isolation of at least $5 \times 10^4$ colonies/mL in Hoberman and coworkers' study [104]. The presence of pyuria and bacteriuria increased positive predictive value for positive cultures in both studies to 85% and 88%.

Studies of neonates with early-onset septicemia indicate that the yield for culture of urine is low [14,15,115,116]. Culture may be eliminated in evaluation of infants

younger than 3 days for presumed sepsis. Examination of urine occasionally can aid in microbiologic diagnosis of early-onset septicemia, but initiation of antimicrobial therapy should not be delayed when there is difficulty in obtaining the specimen or narrowed for spectrum of activity.

## EXAMINATION OF BLOOD

The peripheral blood leukocyte count varies among infants with UTI. Although significantly higher neutrophil and band counts and band-to-neutrophil ratios are documented in young children with UTI, these do not reliably discriminate among presence, absence, or level of infection in the urinary tract or presence of bacteremia [16,17,112]. In studies from New Zealand [5], half of the neonates had a peripheral blood leukocyte count of greater than 16,000/mm$^3$, but no information was given about this measure in uninfected infants. Hemolytic anemia frequently accompanies jaundice when the latter is present in infants with UTI. Result of the direct Coombs test usually is negative. The reticulocyte count can be normal or elevated [82].

Although signs of inflammatory response such as elevated erythrocyte sedimentation rate (ESR) or serum CRP or procalcitonin correlate generally with abnormal renal scintigraphy findings suggestive of acute pyelonephritis in children with UTI, standardized cutoff values for stand-alone positive or negative predictive tests have not been possible. In 64 children studied, Majd and colleagues [57] found abnormal scans in 78% of children with ESR of at least 25 mm/hr compared with 33% of children with lower ESR. Benador and coworkers [56] found that ESR greater than 20 mm/hr or CRP level greater than 10 mg/L had a sensitivity of 89% and specificity of 25% for identifying renal lesions among 73 children with UTI. Stokland and colleagues [117] correlated CRP level greater than 20 mg/L at the time of acute infection with resultant renal scar in 157 children reevaluated 1 year later; sensitivity of elevated CRP was 92%, and positive and negative predictive values were 41% and 80%. In 153 children with fever and positive urine culture (colony count $\geq 5 \times 10^4$/mL), Hoberman and coworkers [112] reported significant correlations between evidence of pyelonephritis versus cystitis versus asymptomatic bacteriuria with mean peripheral WBC count (22,400/mm$^3$ versus 14,600/mm$^3$ versus 11,700/mm$^3$), ESR (44 mm/hr versus 26.8 mm/hr versus 15.3 mm/hr), and CRP (10.1 mg/L versus 2.7 mg/L versus 1.3 mg/L). In a study using cutoff values of 1 ng/mL for procalcitonin and 20 mg/L for CRP, rates of sensitivity for detection of pyelonephritis in infants with UTI were similar (92%), but specificity of procalcitonin (62%) exceeded that of CRP (34%) [118].

## CHEMICAL DETERMINATIONS

Hyperbilirubinemia is present in many infants with UTI; the percentage of conjugated bilirubin often is determined by the age of the infant at the onset of jaundice [81]. During the first week of life, almost all of the bilirubin is unconjugated, but in the second week and thereafter, the fractionation is approximately equivalent. In 80 Boston infants younger than 1 month of age with UTI, 11 (14%) had jaundice and hyperbilirubinemia; only 4 had bacteremia [17]. With the exception of changes in serum bilirubin, the results of serum hepatic enzyme tests generally are normal or only slightly abnormal [81,82]. Azotemia and hyperchloremic acidosis are not unusual; serum bicarbonate measured less than 20 mEq/L in 34.1% of 354 young children with UTI in one study [17].

## IMAGING OF THE URINARY TRACT

The major goal of investigation of the urinary tract in infants with UTI (and infants with abnormalities noted prenatally) is to identify important and correctable lesions (including urethral strictures, renal anomalies, obstructive uropathy, urethral valves in boys, and some cases of severe VUR) and to provide the opportunity to begin antibiotic prophylaxis against recurring UTIs in certain infants with reflux or hydronephrosis in whom surgery is not indicated. (See previous discussion of uncertainty of benefit of antibiotic prophylaxis and surgery for primary VUR or hydronephrosis.) Multiple imaging modalities are available, and each modality provides unique evaluations [55,61,117,119–122]. Ultrasonography can delineate the size, shape, and location of kidneys and contributes to the diagnosis of hydronephrosis, hydroureter, ureterocele, bladder distention, and stones, but less so to VUR. Ultrasonography is the most noninvasive study, and its accuracy is dependent on the experience of the interpreter. It is an insensitive test for pyelonephritis, but sometimes shows kidney enlargement with abnormal echogenicity. Renal ultrasonography performed to follow up on fetal studies should be postponed for at least 48 hours after birth to avoid a false-negative result from dehydration or low glomerular filtration rate characteristic of newborns [119].

Renal cortical scintigraphy using technetium-99m–labeled dimercaptosuccinic acid or gluceptate is the most sensitive test for identifying acute pyelonephritis (i.e., focally or diffusely decreased cortical uptake of tracer without evidence of cortical loss, sometimes in an enlarged kidney) or chronic scarring (i.e., decreased uptake with corresponding cortical volume loss); scintigraphy also provides an estimate of renal function. Scintigraphy is the gold standard for diagnosis of acute pyelonephritis; 66% to 75% of children younger than 2 years with febrile UTI in multiple studies have a positive result [56,57]. Renal scintigraphy at the time of UTI was performed in a multicenter study in Spain. In a subset of infants younger than 30 days of age with community-associated UTI (106 cases) and nosocomial UTI (15 cases), cortical defects were present in 31% and 73%. Although abnormal scintigraphy was significantly associated with abnormal ultrasonography and VCUG, 21% of study infants without either finding had abnormal scintigraphy [4].

Voiding cystourethrography using radiographic or radionuclide methodology is the best study to visualize the bladder and urethra and to detect VUR; radionuclide scan is superior to the dye study for detection of intermittent reflux, but is inferior for detection of urethral and

bladder wall abnormalities and cannot be used to grade VUR. Both are invasive and associated with discomfort attendant with catheterization. A 24-day-old male infant with ureterovesical junction obstruction was found to have *E. coli* septicemia and UTI 6 days after elective vesicourethrography, which did not show VUR [123]. Toxic reaction to the cystourethrography dye can occur in infants but is rare.

Ultrasonography and cystourethrography have been recommended for all neonates with UTI judged to be other than that secondary to septicemia. Male infants with community-associated first UTI diagnosed before 8 weeks of age have a higher incidence of VUR or anatomic abnormalities (22% of 45 male infants in one Israeli study) than that noted in older children [124]. Ultrasonography is performed at the time of infection to identify major renal and ureteral abnormalities. Cystourethrography sometimes can be delayed to permit resolution of inflammatory VUR; however, in clinical studies, less than 50% of children with acute pyelonephritis proved to have VUR [38,57,120].

Renal scintigraphy is useful in diagnosis and management of selective cases of UTI [125,126]. Computed tomography (CT) is performed infrequently, such as when a mass lesion or abscess is suspected. For infants who have undergone prenatal ultrasonography in an experienced center after 30 to 32 weeks of gestation and whose study findings were normal, repeat ultrasonography at the time of first UTI is not recommended by some experts [110,111].

## MANAGEMENT AND PREVENTION

Management of UTI is aimed at halting infection rapidly, reconstituting normal fluid and acid-base status, and assessing medical or surgical interventions required to prevent subsequent episodes of UTI and kidney damage. Antimicrobial agents should be administered as soon as culture specimens of the blood, cerebrospinal fluid (if indicated), and urine have been obtained. The choice of antimicrobial agents for initial therapy and the dosage schedule are the same as outlined in Chapter 6 for septicemia (a penicillin and an aminoglycoside). A penicillinase-resistant penicillin (methicillin or oxacillin) should be used if an abscess of the kidney, prostate, or testis is present, which suggests infection with *S. aureus*. Vancomycin may be appropriate when methicillin-resistant *S. aureus* organisms are prevalent in the community or nursery. Patients who have suspected hospital-acquired infection are frequently given vancomycin and an aminoglycoside as initial therapy because of the significant role of coagulase-negative staphylococci and *Enterococcus* species. The decision to use a third-generation cephalosporin is based on the patient's prior receipt of antibiotics, the patient's clinical state, and the knowledge of bacterial species indigenous in each neonatal intensive care unit.

Extended-spectrum β-lactamase–producing organisms of the family Enterobacteriaceae are increasingly problematic in neonatal nosocomial infections, including UTI. Gram stain of urine sediment is helpful in initiating empirical therapy for UTI, especially when fungal infection is considered. Therapeutic regimens should be reconsidered when the results of cultures and antimicrobial susceptibility tests are available.

Effective antimicrobial agents sterilize the urine within 24 to 48 hours. A second specimen of urine often is obtained for examination and culture at about 48 hours. Persistence of bacteriuria or funguria implies that treatment is ineffective or that a foreign body, fungus ball, or obstruction is present.

The duration of antimicrobial therapy for UTI in neonates usually is 14 days. Longer therapy (up to 3 weeks) is necessary if there is a poor response or if an anatomic or physiologic abnormality suggests that relapse may occur if administration of the drug is not continued. Timing of change from parenterally to orally administered agents depends on rapidity of clinical and microbiologic response and the presence of bacteremia or anatomic, functional, or physiologic abnormalities and availability of a highly active oral agent. Parenteral therapy usually is given for at least 3 to 4 days in uncomplicated cases [127,128]. Clinical vigilance for nonspecific symptoms and signs of illness after conclusion of therapy is important so that recurrent infection can be detected and treated appropriately. Children with certain urinary tract anomalies, functional abnormalities, and higher grades of VUR often are given prophylactic antibiotics continuously for extended periods until the condition improves or surgery is performed [63,119]. (See previous discussion of uncertainty of benefit of standard prophylaxis in primary VUR alone.) A systematic review of randomized controlled trials of prophylaxis revealed limited evidence for its efficacy [129]. A randomized trial in 576 older infants and children in Australia showed statistically significant but modest effect of trimethoprim-sulfamethoxazole over placebo in preventing UTIs (13% measus 19%). [130]. A U.S. multicenter study to test this question is planned [74,75]. Amoxicillin, 20 mg/kg/day divided in doses administered every 12 hours, is the agent most frequently used for prophylaxis in the neonate.

Measures that have been shown to reduce nosocomial UTIs in older children and adults should be applied to newborns. Evidence-based interventions include avoidance of unnecessary urinary catheterization, vigilance in hand hygiene, insertion and maintenance of a catheter in a sterile manner, and discontinuation of catheterization as soon as possible (i.e., daily evaluation of need to continue) [131].

## PROGNOSIS

For patients with UTI and underlying genitourinary abnormalities, long-term control of infection is important. After that, prognosis depends on severity of the lesion and associated congenital renal syndromes. The natural history of UTI in the newborn without underlying abnormality is incompletely described. Some infants with asymptomatic bacteriuria have infection that clears without use of antimicrobial agents [5,6,132]. Some infants with symptomatic infection respond readily to therapy and have no subsequent infections, whereas others have recurrences, although the number seems to be smaller than that for older children and adults. In the series from Göteborg [6] and Leeds [8], recurrences occurred in 26% and 19% of infants; the second

episode usually occurred during the first few months after the initial infection.

It is possible that inflammatory changes in the kidney early in life may lead to subsequent impairment of growth and development of the kidney and to epithelial damage, fibrosis, and vascular changes, but it is uncertain how frequently these events occur. In a study of 25 children with UTI in whom renal scintigraphy showed evidence of acute pyelonephritis and who underwent repeat scanning an average of 10.5 months later, 16 (64%) had corresponding scars [56]. In another study, 38% of 157 children (with median age 0.4 year at the time of asymptomatic UTI) had renal scars documented 1 year later [117]. Infants do not seem to be at increased risk for scarring; in 50 infants younger than 1 year with UTI and abnormality scintigraphy acutely, repeat scintigraphy after an average of 3 months showed scars in 40% [133].

Obstructive lesions associated with reflux during the neonatal period may be associated with progressive renal damage, whereas children with unobstructive reflux regardless of severity infrequently have progressive renal damage. The hypothesis that outcome depends on prevention of infection has been challenged. [74,75] Repeat ultrasonography for follow-up evaluation after UTI in infants in whom findings on a postnatal ultrasound examination were normal is not indicated [134].

CHAPTER 10

# FOCAL BACTERIAL INFECTIONS

Gary D. Overturf

CHAPTER OUTLINE

## INFECTIONS OF THE LIVER

Bacterial infection of the hepatic parenchyma frequently is recognized as multiple, small inflammatory foci (hepatic microabscesses) observed as an incidental finding in infants dying with sepsis. Diffuse hepatocellular damage, often in conjunction with infection of several organ systems, may be present after transplacental passage of microorganisms to the fetal circulation. Liver involvement rarely may take the form of a solitary purulent abscess. Metastatic focal infections of the liver associated with bacteremia resolve with antimicrobial therapy, are not recognized, or are found only at postmortem examination. Rarely, they are clinically apparent as solitary [1] or multiple [2] large abscesses diagnosed during life.

Although metastatic infections are rare, it is difficult to ascertain their true incidence. In a survey of more than 7500 autopsies of children performed from 1917-1967, Dehner and Kissane [3] found only 3 neonates with multiple, small, pyogenic hepatic abscesses, whereas a review of approximately 4900 autopsies [4] performed at Los Angeles Children's Hospital from 1958-1978 revealed 9 infants with pyogenic hepatic abscesses [5]. Among 175,000 neonates admitted from 1957-1977 to Milwaukee Children's Hospital, 2 died with hepatic microabscesses [6]; 3 patients with hepatic microabscesses were seen among 83,000 pediatric patients admitted to New York Hospital from 1945-1983 [7]; and one case of hepatic microabscesses was reported at the University of Texas Medical Branch in Galveston from 1963-1984 [8]. Most reviewers who have discussed postmortem observations of infants dying with neonatal sepsis have not described the occurrence of such secondary sites of infection [9–16] or have presented them as an occasional ancillary finding [17,18].

Solitary hepatic abscesses in newborns have also been reported rarely. About 30 such cases have been described [1,3,4,19–41]. These infections frequently are associated with prematurity and umbilical vein catheterization,* whereas solitary abscesses may occur because of bacteremia. Murphy and Baker [42] described a solitary abscess after sepsis caused by *Staphylococcus aureus*.

### MICROBIOLOGY

The etiologic agents in the infants described by Dehner and Kissane [3], Moss and Pysher [5], Chusid [6], and included *Escherichia coli*, *S. aureus*, *Pseudomonas aeruginosa*,

*References [5,6,21,22,25,28,32,34–41].

DOI: 10.1016/B978-1-4160-6400-8.00010-9

*Klebsiella* species, *Enterobacter* species, and *Listeria monocytogenes*. The causative bacteria of solitary abscesses are generally the bacteria colonizing the umbilical stump [43], including *S. aureus* (11 cases), *E. coli* alone (3 cases), *E. coli* with *S. aureus* (2 cases) or enterococcus (1 case), *Enterobacter* species (3 cases), *Klebsiella pneumoniae* alone (2 cases), *K. pneumoniae* with *Proteus* species (1 case), *P. aeruginosa* (1 case), *Staphylococcus epidermidis* with group F streptococcus (1 case), and *Streptococcus pyogenes* (1 case). In three infants, the abscesses were described as "sterile." [19,28,31] Although one of these infants had received penicillin for 9 days before surgical drainage, it is possible that in all three cases the abscesses were caused by anaerobic bacteria that failed to grow. The presence of gas in seven abscesses [25,28,34,35,39] may indicate infection with anaerobes, a frequent cause of liver abscess in adults [44].

The most common cause of intrauterine bacterial hepatitis, congenital listeriosis, characteristically involves the liver and adrenals (see Chapter 13). Typical lesions are histologically sharply demarcated areas of necrosis (miliary granulomatosis) or microabscesses containing numerous pleomorphic gram-positive bacilli [15]. Descriptions in the early 1900s of miliary necrosis of the liver related to "gram-positive argentophilic rodlike organisms" probably also represented infections with *L. monocytogenes*, which was not isolated and identified until 1926 [26].

Intrauterine tuberculosis results from maternal bacillemia with transplacental dissemination to the fetal bloodstream (see Chapter 18). Because the liver is perfused by blood with a high oxygen content [45] and is the first organ that encounters tubercle bacilli, it is often severely involved [15,44,46]. The presence of primary liver foci is considered evidence for congenital tuberculous infection as a result of hematogenous spread through the umbilical vein [47]. Closed-needle biopsy may be less accurate in the diagnosis of hepatic granulomas, and open biopsy may be required to confirm liver and regional node involvement [48]. Although generalized fetal infection may also arise through aspiration of contaminated amniotic fluid, the lesions acquired in this manner are usually most prominent in the lungs. In addition to hepatomegaly, a clinical picture of fever with elevated serum IgM and chorioretinitis (e.g., choroid tubercles) may be similar to that caused by other congenital infectious agents [49]. In a review by Abughal and coworkers [49], positive sites of culture for tuberculosis included liver (8 of 9), gastric aspirate (18 of 23), tracheal aspirate (7 of 7), ear (5 of 6), and cerebrospinal fluid (3 of 10). Noncaseating granulomatous hepatitis, thought to be caused by a hypersensitivity reaction related to bacille Calmette-Guérin vaccination, has also been described in a neonate [50], but histologic and bacteriologic studies performed on liver biopsy specimens failed to identify the presence of acid-fast bacilli or bacille Calmette-Guérin organisms.

Bacterial infection of the fetal liver rarely has been reported in association with maternal tularemia [51], anthrax [52], typhoid fever [53], and brucellosis [54]. It is uncertain whether the isolation of bacteria from the livers of stillborn fetuses is significantly associated with their clinical course [55,56].

*Treponema pallidum* is the spirochete most commonly associated with transplacental hepatic infection (see Chapter 16). Pathologic changes in the liver, which may be found in 95% of infants dying with congenital syphilis [57], include diffuse hepatitis or focal areas of inflammation, both frequently accompanied by increased connective tissue and enlargement of the liver [15,57–59]. Involvement of liver has also been documented, on the basis of isolation of organisms or their identification in histologic sections, in newborns with intrauterine infection caused by various *Leptospira* species (*Leptospira icterohaemorrhagiae* [60,61], *Leptospira pomona* [62], *Leptospira canicola* [63], *Leptospira kasman* [64]).

Transplacental infection of the fetus with *Borrelia recurrentis* causes little or no inflammation of liver parenchyma or biliary epithelium despite the presence of numerous spirochetes in the sinusoids [65–68]. Congenital infection has been suggested with *Borrelia burgdorferi* [69] (cause of Lyme disease); hepatic, central nervous system, and cardiac lesions may be observed, and widely disseminated lesions were reported to occur in other tissues. This single case is controversial, however, and the American Academy of Pediatrics does not accept congenital Lyme disease because no "causal relationship between maternal Lyme disease and abnormalities of pregnancy or congenital disease caused by *B. burgdorferi* has been documented conclusively" [68a]; no evidence exists that Lyme disease can be transmitted via human milk.

## PATHOGENESIS

Infectious agents may reach the liver of the fetus or newborn by one of several pathways: transplacental or transoral intrauterine infection, extension of thrombophlebitis of the umbilical vein, through the hepatic artery during the course of a systemic bacteremia, pyelophlebitis owing to a focus of infection in the drainage of the portal vein (mesenteric or splenic veins), direct invasion from contiguous structures or because of trauma or surgical inoculation, and extension up the biliary passages in cases of suppurative cholangitis. Abscesses with no apparent focus of infection seem to be common in newborns compared with older children [30]. Three such cases, all in infants with solitary hepatic abscesses, have been described [23,24,31]. Descriptions of the surgical findings, together with the nature of the lesions, suggest that an umbilical vein infection, obscured by the large collection of purulent material in the abscess, was the probable pathogenesis in all infants.

The mode of infection usually determines the pattern of hepatic involvement. Intense and prolonged seeding of the liver parenchyma, such as that which occurs in conjunction with intrauterine infection or neonatal sepsis, almost invariably results in diffuse hepatocellular damage or multiple small inflammatory lesions [3,5,6]. Umbilical vein thrombophlebitis may cause an abscess of the falciform ligament [70] or extend into a single branch of the portal vein to produce a solitary pyogenic abscess,* or it can lead to disseminated foci of infection through dislodgment of septic emboli [6,71–74].

The frequent use of umbilical catheters has been associated with an increase in the numbers of infants

*References [6,21,22,26,29,32,33].

with solitary [5,6,20–22,32,34–40] or multiple [5,75,76] hepatic abscesses. In three large series, including almost 500 infants who died after placement of umbilical vein catheters, 29 infants were found to have purulent infections of hepatic vessels or parenchyma [37,75,77]. Use of venous catheters for infusion of hypertonic or acidic solutions may provide a necrotic focus for abscess formation [21,32,34–36,76,77], and prolonged [5,22,32,77] or repeated [63] catheterization of a necrotic umbilical stump provides an ideal pathway for introduction of pathogenic organisms. It has been postulated that some hepatic abscesses have been caused by infusion of contaminated plasma [28] or by the use of nonsterile umbilical catheters [75].

Although neonatal liver abscesses usually are caused by hematogenous dissemination of bacteria through the hepatic artery or umbilical vein, examples of infection arising from various other sources have been described. Solitary abscesses have followed a presumed portal vein bacteremia caused by amebic colitis [19,20]. Direct invasion of adjacent liver parenchyma from purulent cholecystitis [24] or postoperative perihepatic abscesses [5] also has been observed. Ascending cholangitis, the most frequent cause of hepatic purulent infections in adults [30], has not been implicated in the causes of newborn infections.

Disease caused by embryonic anatomic errors is unique to newborns. Shaw and Pierog [78] described a newborn with umbilical herniation of a pedunculated supernumerary lobe of the liver; histologic examination showed numerous small foci of early abscess formation. Although signs and symptoms of sepsis appeared at 18 days of age, possibly the result of bacterial spread from the liver to the umbilical vein, the infant improved and ultimately recovered after removal of the polypoid mass on the 19th day of life.

Descriptions of “umbilical sepsis” and “acute interstitial hepatitis” recorded by Morison [79] seem to indicate that his patients had acquired bacterial infections of umbilical vessels with widespread extension into portal tracts. Although mild periportal parenchymal necrosis was observed in a few infants, hepatocellular damage was minimal or absent in most. Similar lesions have been found in infants dying with sepsis [80] and infantile diarrhea [81].

## CLINICAL MANIFESTATIONS

Multiple hepatic abscesses and diffuse hepatitis related to neonatal sepsis or transplacental fetal infection are usually recognized only at autopsy. Very few clinical manifestations referable to hepatocellular damage are evident before death. The signs and symptoms associated with these conditions are those of the underlying sepsis or of secondary metastatic complications, such as meningitis, pneumonitis, or peritonitis.*

Solitary abscesses are indolent in terms of their development and clinical presentation. Although the suppurative umbilical focus or umbilical catheterization responsible for the introduction of microorganisms can usually be traced to the 1st week of life, evidence of hepatic involvement is usually not apparent before the 2nd or 3rd week. The abscess frequently becomes a source for the hematogenous dissemination of microorganisms so that most infants have signs and symptoms of a bacteremia. Despite intense infection of the underlying vessels, the umbilical stump usually shows no evidence of inflammation or purulent discharge. The presence of hepatomegaly, a finding commonly associated with neonatal sepsis, also offers little aid in establishing a definitive diagnosis. In one half of infants for whom physical findings are clearly described, a well-delineated, often fluctuant or tender mass could be palpated in the epigastrium or right upper quadrant. On a few occasions, this mass was noticed by the infant’s mother several days before the onset of systemic symptoms. Abscesses occur in the right or left lobe of the liver with almost equal frequency and are generally 3 cm or more in diameter at the time of surgical exploration.

*References [2,3,29,33,72,75].

## DIAGNOSIS

Hematologic studies are of little value in establishing a diagnosis; leukocyte counts and sedimentation rates may be normal or elevated. The serum levels of liver enzymes may also be normal [25,38] or elevated [5,23,36].

Abdominal radiographs are usually normal or show nonspecific displacement of the lower edge of the liver. In five infants, diagnosis was suspected from plain x-ray films by the presence of gas within the hepatic shadow [28,32,34,39]. Radiologic findings that commonly accompany hepatic abscess in older children, such as an altered contour of the diaphragm, right pleural effusion, and platelike atelectasis [82], are rarely present in neonates.

Ultrasonography should be the initial imaging study in newborns with clinical evidence of a hepatic abscess [83–86]. If ultrasound is negative, and the diagnosis is still strongly suspected, more sensitive techniques such as computed tomography (CT) or magnetic resonance imaging (MRI) should be performed [83–88]. Enhancement with contrast agents may increase the definition of smaller abscesses. Because congenital cysts, arteriovenous malformations, and tumors with central necrosis or hemorrhage can mimic hepatic abscess, the diagnosis should always be confirmed by aspiration of purulent material at laparotomy or by means of percutaneous drainage with ultrasound or CT guidance [84,89,90].

## PROGNOSIS

The prognosis for infants with diffuse liver involvement related to fetal or neonatal sepsis depends on the underlying condition because hepatic function is rarely compromised sufficiently to determine the outcome. In most cases, pathologic changes in the liver are unsuspected before postmortem examination.

Of 24 infants with solitary hepatic abscesses whose course was described, 8 died. Two infants died before antibiotics were available [26], and the death of another was ascribed to cecal perforation [20]. Four newborns died with sepsis caused by organisms that were identical to the organisms isolated from the abscess [21,25,33,34]. Prematurity was undoubtedly a major contributing factor in two of these deaths [21,25].

## TREATMENT

Newborns with a solitary hepatic abscess have traditionally been treated with open surgical drainage in conjunction with antibiotic therapy. Percutaneous catheter drainage is less invasive and often is the preferred first treatment. Several investigators have described the use of percutaneous drainage of intrahepatic abscesses and cysts, guided by CT or ultrasonography, in neonates [41,75,90] and children [7,84,89]. When combined with antibiotic therapy and monitored by ultrasound to ensure resolution, this treatment has been highly effective. It is questionable whether drainage contributed to recovery other than by aiding the selection of antibiotic coverage. Subsequently, patients have been successfully treated with empirical antibiotic therapy alone [91,92]. Conservative medical management in infants has been described in only two neonates and a 5-month-old infant [33,37,78].

The risk of bacteremia and disseminated infection is high in neonates, and the need to identify infecting organisms to guide antibiotic coverage is of greater urgency in the first weeks of life. It is appropriate to ascertain a microbiologic diagnosis with radiographically guided aspiration or drainage of hepatic abscess in a newborn. When proper equipment (e.g., CT, ultrasonography) and experienced personnel are available, this can be attempted percutaneously [89,90]. When they are unavailable, open surgical drainage should be performed. Empirical antibiotic therapy should be reserved only for infants for whom it is believed that the risk of open or closed drainage would exceed the potential benefits.

If purulent material is obtained, initial antibiotic therapy can be selected on the basis of Gram stain. In addition to *S. aureus* and the aerobic enteric organisms commonly associated with hepatic abscesses, anaerobic bacteria have been suspected as the cause of infection in numerous patients.* If foul-smelling pus is aspirated or if Gram-stained smears show organisms with the characteristic morphology of anaerobes [33], metronidazole, β-lactam and β-lactamase inhibitor combinations (e.g., piperacillin and tazobactam), clindamycin, or imipenem should be included in the initial regimen. Cultures of blood, cerebrospinal fluid, and urine should also be considered before initiation of therapy.

If empirical antibiotic therapy is required, it must be adequate for infections caused by *S. aureus*, enteric organisms, and anaerobic bacteria. The combination oxacillin, gentamicin, and clindamycin is appropriate. In nurseries where methicillin-resistant *S. aureus* (MRSA) or methicillin-resistant *S. epidermidis* infections have been a problem, substitution of vancomycin for oxacillin can provide coverage for these organisms. Gentamicin (and other aminoglycosides) and vancomycin levels must be monitored and dosages adjusted as necessary. Extended-spectrum cephalosporins (e.g., cefotaxime, cefepime, ceftazidime) and carbapenems (e.g., meropenem) may be used for enteric organisms and *Pseudomonas* species, often obviating the need for aminoglycosides. β-lactam and β-lactamase inhibitor combination drugs (e.g., piperacillin and tazobactam or ampicillin and sulbactam) may provide coverage for many enteric organisms and anaerobic bacteria.

Definitive therapy is based on results of bacteriologic cultures that identify the bacteria and its antibiotic susceptibility. Adequate anaerobic transport and culture techniques must be available if meaningful information is to be obtained. Duration of treatment is based on clinical response, cessation of drainage, and resolution of the abscess cavity as determined by serial ultrasound examinations. Parenteral therapy should be maintained for at least 2 weeks and longer term therapy may be administered when necessary. In older children with multiple abscesses or in children for whom surgery is not feasible, therapy for 6 weeks or more has been recommended.

## SPLENIC ABSCESS

Similar to hepatic abscesses, splenic abscesses have been rarely described in infants [93]. Only 1 of 55 splenic abscesses occurred in an infant younger than 6 months. *S. aureus*, *Candida* species, and streptococci were the most frequent causes. In 20 of 48 cases, hepatic abscesses coexisted with splenic abscess. In the single infant case, torsion of the splenic vessels was present, whereas in older children, other distant infections of hematologic conditions (e.g., hemoglobinopathy, hematogenous malignancy) were the associated comorbid conditions.

## INFECTIONS OF THE BILIARY TRACT

The development of ultrasonography has provided a safe and rapid means for evaluating the neonatal biliary tract. Consequently, an increasing number of reports have appeared describing ultrasound changes seen in the first month of life, with hydrops [94,95], cholelithiasis [95–100], and transient distention of the gallbladder associated [94,95,99,101–104] or unassociated [99,102,103,105–108] with sepsis. Ultrasound criteria for separating normal from pathologically enlarged gallbladders and biliary tracts in neonates have also been described [109,110].

Despite advanced technology and increased surveillance, cholecystitis in the neonate is observed infrequently. The literature has documented about 25 cases, of which 9 were seen in association with an epidemic of neonatal enteritis caused by *Salmonella enteritidis* [111]. Of the remaining infants, 16 were the subjects of isolated case reports [24,103,112–123], and 3 died of other causes with inflammatory changes in the gallbladder described as an incidental finding at autopsy [81,95,124]. A tissue diagnosis of "chronic cholecystitis" was established in an infant whose biliary disease apparently began at 6 days of age [125].

The pathogenesis of this condition is uncertain; all but three cases [99,118,122] of cholecystitis in the newborn period have been acalculous. It is postulated that sepsis, dehydration, prolonged fasting (e.g., total parenteral nutrition), congenital obstruction, or a stone impacted in the cystic duct leads to biliary stasis and acute distention of the gallbladder. In most cases, resolution of the primary process permits restoration of the flow of bile and relief of distention. In some cases, prolonged obstruction leads to hydrops [94]. Cholecystitis rarely follows, perhaps because of a direct toxic effect of retained bile or because of ischemia related to elevated intraluminal

*References [25,28,32,33,35,39].

pressure. Bacterial invasion by fecal flora is probably a secondary phenomenon [114,115,126]. Organisms that have been isolated from gallbladder contents or tissue include *E. coli* [114–116,123], *Serratia marcescens* [103,117], *Pseudomonas* species [115], *Streptococcus faecalis* [123], viridans streptococci [121], *S. aureus* [123], and *Clostridium welchii* [123]. "Gram-positive cocci" were identified by Gram stain in one patient [113].

Infants with cholecystitis may become ill at any time during the first weeks of life; most cases are diagnosed in the 3rd or 4th week. The typical clinical picture is one of sepsis together with signs of peritoneal inflammation and a palpable tender right upper quadrant or epigastric mass. Diarrhea frequently accompanies these findings. Although ultrasonography and radionuclide scintigraphy are helpful in suggesting the presence of gallbladder enlargement or inflammation, diagnosis can be confirmed only by surgical exploration [94,102,103,106,108]. Treatment consists of cholecystectomy or tube cholecystotomy combined with systemic antimicrobial therapy based on Gram stain, culture, and susceptibility studies. If a T tube is placed in the gallbladder, a cholangiogram should be obtained to confirm patency of the biliary system before the tube is removed.

Changes compatible with a diagnosis of ascending cholangitis have been described in histologic sections of liver specimens from infants who died with diarrhea accompanied by hepatocellular injury with cholestasis [91]. Bacteria were also identified in the biliary tree of 2 of 178 premature infants who died after placement of an umbilical venous catheter for an exchange transfusion or for delivery of parenteral fluids [75]. The reasons for this association, if any, are unclear. An infant with spontaneous cholangitis caused by *Enterobacter agglomerans*, presenting as a fever of unknown origin at 3 weeks of age, has also been reported [127].

Severe inflammation and fibrosis of extrahepatic bile ducts and diffuse changes in the portal tracts, resembling changes found in biliary atresia, were found in a premature infant who died 3 hours after birth of listeriosis [128]. The investigator postulated that occult prenatal infections with *L. monocytogenes* might be a rare cause of ascending cholangitis manifesting as idiopathic biliary atresia at birth.

## INFECTIONS OF THE ADRENAL GLANDS

Multiple adrenal microabscesses are occasionally found as metastatic lesions associated with neonatal sepsis. These abscesses are particularly characteristic of neonatal listeriosis (see Chapter 13). Solitary adrenal abscesses are rare, however; only about 25 such cases have been described [17,129–150].

The spectrum of organisms responsible for adrenal abscesses is the same as that seen in neonatal sepsis and includes *E. coli* (seven cases) [17,129,130,135–138], group B streptococci (GBS) (four cases) [138–141], *Proteus mirabilis* (three cases) [131,132,144], *S. aureus* [142,143], *Bacteroides* species [133,145], and two cases each of *Streptococcus pneumoniae* with *Bacteroides* species [134]; *Peptostreptococcus* species [146] was recovered from one case. Drainage of foul-smelling pus at surgery suggests that anaerobic bacteria may have been present in two infants from whom *E. coli* and *S. aureus* were isolated [136,142]. Cultures were not obtained from four patients [147–150].

Fourteen abscesses were located on the right side, seven were located on the left, and three [138,139,147] were bilateral. Three fourths of the infants were male. The same laterality and sex predominance are seen with adrenal hemorrhage in the newborn [147,150–152], and it has been postulated that formation of an adrenal abscess requires a preexisting hematoma as a nidus for bacterial seeding [137,138]. This theory of pathogenesis is supported further by clinical observations[134,135,139,146,147] and by objective evidence (e.g., curvilinear calcifications [130,132] documenting the presence of hemorrhage before development of an abscess [134,138,142,145,150].

Most infants with adrenal abscess have presented in the 3rd or 4th week of life with signs of sepsis and an abdominal or flank mass. A history of difficult delivery or intrapartum asphyxia was observed in about one half of these infants, and significant maternal fever or infection during labor was observed in about one fourth [138,140,141,150]. Although a few infants are afebrile when first evaluated, a palpable mass is almost always present. Abscesses are usually 6 to 8 cm in diameter, with some containing 200 mL of pus [133] and measuring 12 cm in diameter [134] or crossing the midline [146].

Laboratory studies are helpful in the evaluation of a possible adrenal abscess. Most infants exhibit a leukocytosis; about one third are anemic with a history of prolonged neonatal jaundice, both of which are features associated with adrenal hemorrhage. Urinary excretion of catecholamines and their metabolites (particularly vanillylmandelic acid and homovanillic acid), which is usually increased with neuroblastoma, is normal. Because most infants with adrenal abscess are seen for evaluation of possible sepsis, a blood culture, lumbar puncture, urine culture, and chest radiograph should be obtained.

Ultrasonography has become a widely accepted modality for initial evaluation of all neonatal abdominal masses. With the presence of an adrenal abscess, ultrasound examination can help to define the extent and cystic nature of the lesion and often can show movable necrotic debris in the abscess cavity.* With serial examinations, abscesses can be distinguished from masses associated with liquefying hematoma, adrenal cyst, hydronephrosis of an obstructed upper pole duplication, or necrotic neuroblastoma [138,140,150,153,154]. Intravenous pyelography shows downward displacement of the kidney and compression of the upper calyces, which confirms the presence of a suprarenal mass.† A round, suprarenal, radiopaque halo or rim with central lucency, which is characteristic of adrenal abscess, may also be seen on early films [137,139,143], but is not pathognomonic [138]. Intravenous pyelography adds little diagnostic information to that provided by ultrasound studies. Experience with radionuclide scanning [140,142,143], CT [138,144], and

*References [132,137,138,141,142,144–148].

†References [130–132,134,136,138,141,142,144–146,149].

MRI [126] in this condition is limited, but these modalities are likely to be as useful as ultrasonography.

Whatever diagnostic methods are used, concern about persisting signs of sepsis and the possible presence of an adrenal neoplasm usually encourage early efforts to establish a diagnosis. In the past, recommended management has been incision and drainage or resection of the abscess [134,138,141,144,150]. Needle aspiration under ultrasound guidance, combined with placement of a catheter for drainage and irrigation, has proved to be a useful alternative method [88,130,131,143] and is likely to supplant open drainage as the preferred method. Antibiotic therapy should be based on Gram stain, culture, and susceptibility studies of abscess fluid and should be continued for 10 to 14 days, provided that drainage can be established.

The adrenals are infected in about 15% of infants with congenital syphilis [57,58]. In addition to the presence of spirochetes, the most frequent and characteristic change is an extraordinary amount of cellular connective tissue in the capsule.

## APPENDICITIS

Acute appendicitis is extremely rare in infants younger than 4 weeks of age. Reviews of more than 25,000 cases of appendicitis in infants and children in Great Britain [155], Ireland [156], Norway [157], Germany [158], and the United States [159–164] revealed only 8 infants who presented during the neonatal period. Pediatric surgery centers in Germany [165], Boston [166], Cleveland [167], Chicago [168], and Detroit [169] found only four cases of neonatal appendicitis. Since the condition was first described by Albrecht in 1905 [170,171] and Diess in 1908 [172], approximately 65 cases of neonatal suppurative appendicitis have been reported in the literature with sufficient details to permit characterization of the clinical features [155,160,161,164,173–210]. Infants with appendicitis caused by other conditions, such as Hirschsprung disease [211,212], necrotizing enterocolitis (NEC) [213], or incarceration in an inguinal hernia [214,215], have not been included in this discussion. An additional 25 to 30 cases that have been reported with incomplete clinical observations, listed in series of patients with neonatal peritonitis (see "Peritonitis") or mentioned in other review articles but unavailable for analysis, are also not included.

Inflammation of the appendix is more common in newborn boys than newborn girls. In reports in which the sex was stated, 40 cases occurred in boys, and 17 cases occurred in girls. Prematurity also seems to be a predisposing factor: 23 of the 49 infants whose birth weights were recorded weighed less than 2500 g at birth. The incidence of appendicitis in infants of multiple births (six twins and one triplet) seems to be higher than would be expected on the basis of low birth weight alone.

### MICROBIOLOGY

Because obstruction of the appendiceal lumen is responsible for almost all cases of appendicitis [166], it is intuitive that gram-negative enteric organisms resident in the bowel are usually isolated from the peritoneal fluid or periappendiceal pus of about 75% of infants. Specific etiologic agents include *E. coli*, *Klebsiella* species, *Enterobacter* species, *Pseudomonas* species, *Proteus* species, untyped streptococci, *S. aureus*, and *Bacteroides* species These bacterial species have also been isolated from the peritoneal fluid of older children with appendicitis [163,166,216]. Attempts at isolation of anaerobic bacteria have been rarely described.

A single case of perforated amebic appendicitis with secondary bacterial peritonitis and multiple hepatic abscesses in a premature infant born in Great Britain has been reported. *Entamoeba histolytica* observed in the wall of the necrotic appendix was presumably acquired from the infant's father, who was a carrier [20]. A patient with gangrenous appendicitis associated with *Rhizopus oryzae* has also been reported [217]. It was postulated that the fungus colonized the infant's gut by transfer from an adhesive bandage used to secure an endotracheal tube.

### PATHOGENESIS

Obstruction of the appendiceal lumen has been generally accepted as the primary cause of appendicitis in all age groups. The relative rarity of this condition in the first month of life is probably related to factors that serve to decrease the likelihood of obstruction, including a wide-based, funnel-shaped appendix; the predominantly liquid and soft solid diet given to infants; the absence of prolonged periods in the upright position; and the infrequency of infections that cause hyperplasia of the appendiceal lymphoid tissue [163,218,219].

The causes of luminal obstruction in the newborn period, when recognized, are often extrinsic to the appendix itself. Reports of appendicitis caused by the presence of ectopic pancreatic tissue [160], a fecalith [174], or meconium plug [167] are unusual exceptions. In 1911, it was suggested that sharp angulation of the appendix, bent on itself in the narrow retrocolic space, may be an important cause of obstruction [220]; however, this anatomy, found in 11 neonates with inflammatory changes in the appendix and noted among 200 consecutive autopsies in infants younger than 3 months at death, has not been repeated in the past 80 years.

Inflammation of the appendix with perforation has been described as the presenting illness in several infants with neonatal Hirschsprung disease [211,213]. The association of these two conditions has been attributed to functional obstruction, increased intraluminal pressure, and fecal trapping that occur proximal to aganglionic segments. Suppurative appendicitis related to incarceration and strangulation of the cecum within an inguinal or scrotal hernia has been found in numerous infants [214,215].

### CLINICAL MANIFESTATIONS

The onset of neonatal appendicitis generally occurs during the first 2 weeks of life. Only 3 of 54 infants with this condition presented between the 1st and 10th day. The reasons for this phenomenon are unclear, particularly in view of the relatively even distribution of cases during the remainder of the 1st year of life [164]. Five cases of

"prenatal" appendicitis have been described [221–225]. Of the four available for analysis, only one showed definite evidence of a suppurative process in the appendix and signs of bowel obstruction clearly present at birth [221]; however, cultures and Gram stain of the pus found at surgery were free of bacteria. Poisoning by mercuric chloride was suspected in one [223] of the remaining three cases, and the other two, who were said to have prenatal rupture of the appendix, were asymptomatic until the 2nd [221] and 12th [225] days of life.

The signs of neonatal appendicitis correspond to the signs of any of the various forms of intestinal obstruction that occur during the newborn period (Table 10–1) [225]. Prominent early findings include abdominal distention; progressive and frequently bilious vomiting; and evidence of pain, as manifested by persistent crying, irritability, or "colic." Clinical features such as diarrhea, constipation, lethargy, or refusal to feed may also be evident, but are too nonspecific to be helpful in establishing a diagnosis. The presence or absence of fever is an unreliable sign in appendicitis as in other forms of neonatal infection; temperature has been recorded as normal or subnormal in more than 50% of newborns with this condition. Abdominal tenderness and guarding are inconsistent findings and, when present, are rarely localized to the appendiceal area. Physical signs of sufficient specificity to indicate acute inflammation of the appendix are generally absent until late in the course of the illness, when gangrene and rupture may result in the formation of a localized intra-abdominal abscess or cellulitis of the anterior abdominal wall. Erythema or edema, or both, of the right lower quadrant has been observed in several patients. The presence of this finding, particularly when accompanied by a palpable mass in the right iliac fossa, indicates bowel perforation with peritonitis and should suggest a preoperative diagnosis of NEC or appendicitis (see "Necrotizing Enterocolitis").

## DIAGNOSIS

The diagnosis of appendicitis in a neonate is usually determined at surgery performed for evaluation of abdominal distention and suspected peritonitis. With the high incidence of prematurity associated with early appendicitis, bowel perforation from NEC has been a common preoperative consideration [206]. The two conditions can coexist, and in some cases, the appendix may participate in the process of ischemic necrosis and perforation [205,213].

**TABLE 10–1** Signs of Intra-abdominal Neonatal Appendicitis in 55 Infants

| Sign | Incidence (%) |
|---|---|
| Abdominal distention | 90 |
| Vomiting | 60 |
| Refusal of feedings | 40 |
| Temperature $\geq 38°$ C | 40 |
| Temperature 37-38° C | 30 |
| Temperature $\leq 37°$ C | 30 |
| Pain (crying, restlessness) | 30 |
| Lethargy | 30 |
| Erythema/edema of right lower quadrant | 25 |
| Mass in right lower quadrant | 20 |
| Diarrhea | 20 |
| Passage of bloody stools | 20 |

Laboratory studies are of little value in establishing a diagnosis of appendicitis in a newborn. White blood cell counts of less than 10,000/mm$^3$ were found in 10 of 30 infants. Urinalyses are usually normal, although ketonuria, which reflects diminished caloric intake; hematuria; and proteinuria may be seen. Because bacteremia may accompany appendiceal perforation and peritonitis, a blood culture and evaluation for metastatic infection with lumbar puncture and chest radiography should be performed. The value of paracentesis for diagnosis of bowel perforation and peritoneal infection is discussed later (see "Necrotizing Enterocolitis").

Radiologic examinations are occasionally helpful, but in most cases serve only to confirm a clinical impression of small bowel obstruction. The presence of an increased soft tissue density displacing loops of intestine from the right iliac fossa generally indicates appendiceal perforation with abscess formation and is perhaps the most reliable sign of acute appendicitis in the neonate. Extraluminal gas may be localized briefly to the right lower quadrant after rupture of the appendix [211]. The rapid development of an extensive pneumoperitoneum obscures the site of origin of the escaping gas in most infants within a short time [226]. Ultrasonography may aid in detection of a periappendiceal abscess [83], but is not helpful in establishing an early diagnosis of appendicitis because it lacks sensitivity and specificity.

## PROGNOSIS

The overall mortality rate from appendicitis in the newborn is high, but is improving. Eight of the newborns in the last 12 reported cases have survived, whereas of 60 infants with this condition for whom the outcome was recorded, 38 (64%) died. Survival was unrelated to birth weight. Among factors responsible for mortalities, three seem to be of primary importance: delay in diagnosis, a high incidence of perforation, and the rapid onset of diffuse peritonitis after appendiceal rupture.

Perforation has been identified at surgery or autopsy in 70% of newborns with acute appendicitis. The relative frequency of this complication has been attributed to delays in establishing a diagnosis and to certain anatomic features of the appendix in young infants that predispose it to early necrosis and rupture. These features include a meager blood supply that renders the organ more vulnerable to ischemia; a cecum that is relatively smaller and less distensible than that of adults, forcing a greater intraluminal pressure on the appendix; and the presence of a thin muscularis and serosa that readily lose their structural integrity under the combined effects of ischemia and increased internal pressure [163,181,182,191].

After the appendix ruptures, infants are unable to contain infection efficiently at the site of origin. Rapid dissemination of spilled intestinal contents produces a diffuse peritonitis within hours because of the small size

of the infant's omentum, which fails to provide an efficient envelope for escaping material; the relatively longer and more mobile mesenteries, which favor widespread contamination; and the small size of the peritoneal cavity, which also permits access of infected material to areas distant from the site of perforation [160,166,181,182]. Peritonitis, accompanied by sepsis and by the massive outpouring of fluids, electrolytes, and proteins from inflamed serosal surfaces, is generally the terminal event in neonatal appendicitis. Deterioration of the infant's condition is often extremely rapid; failure to recognize the underlying illness and to institute appropriate therapy promptly is inevitably followed by a fatal outcome.

### TREATMENT

Surgical intervention is essential for survival of young infants with appendicitis. Because vomiting, diarrhea, and anorexia frequently accompany this condition, restoration of fluid and electrolyte balance is a major factor in ensuring a favorable outcome. Loss of plasma into the bowel wall and lumen of the dilated intestine may require additional replacement with whole blood, plasma, or an albumin equivalent. Optimal preparation often necessitates a delay of several hours, but is a major determining factor in the success of any surgical procedure done during the neonatal period.

The preoperative use of antibiotics has been recommended in infants with intestinal obstruction to achieve therapeutic blood levels of drug before the time of incision and possible contamination [167,227,228]. Perforation, fecal spillage, and peritonitis occur so early in the course of neonatal appendicitis that almost all infants with this condition require treatment before surgery. After the diagnosis of gangrenous or perforated appendicitis has been established and surgery has been performed, parenteral antibiotic therapy should be continued for a minimum of 10 days. The combination of clindamycin (or metronidazole), gentamicin (or extended-spectrum cephalosporins), and ampicillin provides adequate coverage against most enteric pathogens and can be used for initial empirical therapy. Alternatively, β-lactam and β-lactamase inhibitor combinations such as piperacillin and tazobactam or carbapenem antibiotics (e.g., imipenem or meropenem) can be used alone for broad coverage of enteric bacteria, *Pseudomonas* species, and anaerobic bacteria. Until the infant is able to tolerate alimentation, careful attention to postoperative maintenance of body fluids, electrolyte balance, nutrition, and correction of blood and plasma losses is vital to survival (see "Peritonitis" and "Necrotizing Enterocolitis").

## PERITONITIS

Peritonitis in the newborn is most commonly associated with perforation of the gastrointestinal tract, ruptured omphaloceles, or wound infections that follow abdominal surgery [229,230]. It has been estimated that 20% to 40% of gastrointestinal surgical problems in the neonatal period are complicated by bacterial peritonitis (see "Necrotizing Enterocolitis") [185,231]. At pediatric surgical centers in the United States [231–233], Great Britain [230,234], Hungary [235], Germany [236,237], France [238], and Zimbabwe [239], 1 to 10 cases per year have been reported in retrospective analyses of peritonitis diagnosed during the first month of life. Among almost 3000 infants admitted to a neonatal intensive care unit (NICU) in Liverpool in 1981-1982, there were 6 cases of peritonitis, all from NEC perforation of the gastrointestinal tract [240]. Peritonitis was present in 4 (all of low birth weight) of 501 infants on whom consecutive autopsies were performed from 1960-1966 at St. Christopher's Hospital for Children in Philadelphia. These cases represented approximately 3% of all patients with inflammatory lesions associated with death in this age group [241]. Potter [15] considered the peritoneum "one of the most frequent points of localization" in infants dying with sepsis. Among 121 such infants autopsied from 1976-1988 at St. Mary's Hospital in Manchester, England, generalized peritonitis was found in 9 (7.4%) [230].

A preponderance of boys (2.5:1) [190,239,240] and a high incidence of prematurity (33%)[231,234–236] have been found in unselected series of infants with this condition. These features are probably less a characteristic of bacterial peritonitis in the newborn than of the primary surgical and septic conditions that are responsible for its occurrence (particularly NEC). There seems to be a female preponderance among newborns with primary peritonitis [235,242]. A high incidence of congenital anomalies not involving the intestinal tract has also been observed among neonates with peritonitis [231,236,243,244].

### MICROBIOLOGY

The condition that permits bacteria to colonize the peritoneal surface determines the nature of the infecting organisms. Most infants in whom rupture of a viscus and fecal spillage have caused peritonitis are infected by bacteria considered to be part of the normal enteric microflora; however, prior use of antimicrobial agents and colonization patterns within a nursery are important factors in determining which organisms predominate. Although a mixed flora of two to five species can often be recovered [243], single isolates have been reported in a third of infants with peritonitis [245,246]. The predominant aerobic organisms usually include *E. coli*, *Klebsiella* species, *Enterobacter* species, *Pseudomonas* species, *Proteus* species, coagulase-negative and coagulase-positive staphylococci, ungrouped streptococci, *Enterococcus*, and *Candida* [230,231,237,239,246–248].

Techniques adequate for the isolation of anaerobic organisms have been used infrequently. In a series of 43 consecutive infants with gastrointestinal perforation and bacterial growth from peritoneal fluid, a mixed aerobic-anaerobic flora was isolated with *Bacteroides* species as the predominant anaerobes [243]; remaining specimens grew aerobic or facultative organisms alone, and no culture yielded only anaerobes. In that series and others, the same organisms were frequently isolated from the peritoneal cavity and blood [232,243,244,248].

In contrast to fecal flora isolated from infants with gastrointestinal perforation, gram-positive organisms predominated among neonates with "idiopathic primary peritonitis." This condition is caused by sepsis in most

cases, but it also has often been associated with omphalitis. Specific organisms in one representative series included *S. pneumoniae* (three cases); ungrouped β-hemolytic streptococcus (three cases); and *S. aureus*, *Pseudomonas* species, and *E. coli* (one case each) [231]. Gram-positive cocci were also the major isolates in other series of peritonitis associated with hematogenous dissemination of organisms or extension from a peripheral suppurative focus.* Many of the cases caused by *S. aureus* occurred before the advent of antibiotics or during the worldwide pandemic of staphylococcal disease in the late 1950s, whereas streptococci, particularly GBS, have been a prominent cause in recent years [242,249–253].

Rarely, peritonitis may be caused by *Candida albicans* in pure culture or mixed with gram-negative enteric organisms [230,254]. Because clinical findings in this condition are not different from the findings of bacterial peritonitis, the diagnosis is usually established by blood or peritoneal fluid culture. Severe hypothermia has been described as a possible predisposing cause of bowel perforation and peritonitis owing to *Candida* [255]. In addition to well-recognized risk factors, such as prematurity, antibiotic therapy, and parenteral nutrition with deep venous catheters, NEC may be a significant risk factor for systemic candidiasis, in which it was observed in 37% of 30 infants [256]. Only a single infant in this series had a positive culture for *Candida* species from the peritoneum, however. Peritoneal catheters or peritoneal dialysis may also be a risk for direct inoculation of *Candida* organisms into the peritoneal space, which occurred in 1 of 26 children [257] (see Chapter 33).

## PATHOGENESIS

Acute bacterial peritonitis may occur whenever bacteria gain access to the peritoneal cavity, through intestinal perforation, by extension from a suppurative focus, or by the hematogenous route. Intrauterine peritonitis owing to *L. monocytogenes* has been reported [230]; however, cases of "fetal peritonitis" described in earlier reports were actually examples of meconium peritonitis caused by intrauterine intestinal perforation [258,259]. Although bacterial colonization of the gastrointestinal tract in the first days of life may lead to infection in this condition, it is an aseptic peritonitis in its initial stages. A similar condition with focal perforation of the ileum or colon occurring postnatally has been described in infants with very low birth weight. Blue-black discoloration of the abdomen, caused by meconium staining of the tissues of the underlying skin, may be the first physical finding in these infants. Clinical, radiographic, and histopathologic evidence of infection or inflammation was notably absent in most cases [228].

Conditions that predispose to neonatal peritonitis are outlined in Table 10–2. Among almost 400 newborns with peritonitis studied from 1959-1978, perforation of the intestinal tract was responsible for 72% of cases, with ruptured omphaloceles or gastroschisis responsible for 12%, hematogenous dissemination or "primary" peritonitis responsible for 12%, and omphalitis and postoperative complications responsible for 2% each.* In a comprehensive review of neonatal peritonitis, Bell [229,243] described common sites and causes of gastrointestinal perforation and their relative frequencies (Figs. 10–1 and 10–2).

No cases of neonatal peritonitis in recent years have been attributed to microorganisms entering the peritoneal cavity by traversing the bowel wall through the lymphatics or within macrophages (i.e., transmural migration). Evidence for the existence of this pathway is theoretical and is based primarily on retrospective analyses of pathologic data in humans with supporting observations made on laboratory animals [262,263]. Further confirmation is necessary before the transmural pathway can be accepted as an established source of peritoneal colonization by bacteria.

## CLINICAL MANIFESTATIONS

Neonatal peritonitis is a disease primarily of the first 10 days of life; numerous infants have evidence of peritoneal infection within the first 24 hours [231,232,239,244]. An analysis of etiologic factors responsible for peritonitis in the newborn provides a ready explanation for this observation (see Table 10–2). Most cases of NEC [243,264] and spontaneous gastric perforation [232,243,248,260] occur within the 1st week. Ruptured omphaloceles and gastroschisis often develop early infections, and in infants with congenital obstruction, the onset of alimentation during the first 12 to 24 hours accentuates distention and ischemic necrosis of the bowel wall, which leads to early intestinal perforation. Exchange transfusions are performed most frequently within the first 1 or 2 days of life and may be followed by enterocolitis within 4 to 24 hours in infants in whom perforation ultimately occurs [265,266]. Neonatal sepsis, with potential peritoneal seeding of microorganisms, is more frequent during the first 48 hours of life than during any subsequent period [267].

The various signs and symptoms present in a young infant with peritonitis were summarized most succinctly by Thelander [248] in 1939:

"The little patient looks sick. He is cyanotic; the respirations are rapid and grunting; the abdomen is distended, and the abdominal wall, the flanks and the scrotum or vulva are usually edematous. Frequently brawny induration of the edematous area, which may resemble erysipelas, is also present. Food is taken poorly or not at all. Vomiting is frequent and persistent. The vomitus contains bile and may contain blood. The stools are either

**TABLE 10–3** Signs of Bacterial Peritonitis in the Neonate*

| Sign | Incidence (%) |
|---|---|
| Abdominal distention | 85 |
| Shock | 80 |
| Vomiting | 70 |
| Constipation | 60 |
| Hypothermia | 60 |
| Respiratory distress | 55 |
| Fever | 15 |
| Diarrhea | 15 |

**Data are based on patients described in references 232, 240, and 243. Redness, edema, and induration of the anterior abdominal wall, noted in only one series [243], are also recognized as characteristic signs.*

absent or scant; some mucus or blood may be passed. The temperature may be subnormal, but varying degrees of fever have been reported. The blood count is of little or no value. The hemoglobin content may be very high, which probably indicates only dehydration. The leukocytes may or may not respond with a rise."

Although the review by Thelander [248] was limited to neonates with perforation of the intestinal tract, subsequent reports have corroborated the presence of these findings in infants with peritonitis resulting from a wide variety of causes.* Not all of the symptoms described may be encountered in any one patient; however, some are always present (Table 10–3).

The large overlap between signs of neonatal peritonitis and sepsis can make it difficult to differentiate the two on the basis of clinical findings. Signs of intestinal obstruction such as abdominal distention and vomiting, which are seen in 10% to 20% of newborns with sepsis [9,17,244], may reflect a coexistent unrecognized peritonitis. Because the early use of antibiotics often cures hematogenous peritonitis in infants with septicemia, the diagnosis may be missed in infants who survive. Peritonitis unassociated with perforation was found at postmortem examination in 4 of 20 infants with sepsis in 1933 [10], 9 of 73 premature infants dying with septicemia from 1959-1964 [9], and 9 of 121 infants with septicemia dying from 1976-1988 [229].

## DIAGNOSIS

Ultrasonography [83] or abdominal radiographs taken in the erect and recumbent positions showing free intraperitoneal fluid can be helpful in the diagnosis of peritonitis, and sometimes the only evidence of perforation is apparent on these imaging studies. Absence of definition of the right inferior hepatic margin, increased density of soft tissue, and the presence of "floating" loops of bowel have been recorded as positive signs of ascites [226,268]. Diagnostic paracentesis can be useful in determining whether the fluid is caused by bacterial peritonitis [242,251,269,270], hemoperitoneum, chylous ascites [271], or bile peritonitis [272].

*References [190,231,233–235,239,243,248].

The left lateral ("left-side down") decubitus film is of great value in showing small amounts of intraperitoneal gas [243]. Although pneumoperitoneum can be caused by mediastinal air dissecting from the chest into the abdomen [273,274], free gas in the peritoneal cavity usually indicates intestinal perforation. An associated pneumatosis intestinalis should suggest the diagnosis of NEC, but is not specific for this condition. Several patterns of intraperitoneal gas distribution have been described [83,265–276]: the air-dome sign, falciform ligament sign, football sign, lucent-liver sign, saddlebag sign, and gas in the scrotum. Absence of a gastric air-fluid level on an erect abdominal radiograph, with a normal or decreased amount of gas in the small and large bowel, strongly favors a diagnosis of gastric perforation [276]. This finding is almost always accompanied by pneumoperitoneum.

In equivocal cases, metrizamide contrast studies of the bowel can be helpful in establishing a diagnosis of intestinal perforation [245,273]. Serial abdominal transillumination with a bright fiberoptic light is a useful bedside method for the early detection of ascites or pneumoperitoneum in the newborn [277].

Failure to show free air in the peritoneal cavity does not rule out a diagnosis of perforation, particularly if air swallowing has been reduced or prevented through orotracheal intubation, nasogastric suction, or use of neuromuscular blocking agents [269,273,278]. In some cases, the amount of gas in the bowel lumen is so small that even if perforation occurs, the gas could escape detection. Alternatively, small leaks may become walled off and the free air reabsorbed [273,279,280]. In three large series of infants with peritonitis in whom a patent site of perforation was found at surgery, pneumoperitoneum was absent in 35% to 75% [231,243,244].

Radiographic evidence of intestinal obstruction, although a common cause or consequence of peritonitis, lacks sufficient specificity to be a consistent aid to diagnosis. A diffuse granular appearance of the abdomen, with one or more irregular calcific densities lying within the bowel lumen or in the peritoneal cavity, should suggest a diagnosis of meconium peritonitis with possible bacterial superinfection [259].

## PROGNOSIS

Prematurity, pulmonary infections, shock, and hemorrhage related to perforation of the intestinal tract, sepsis, and disseminated intravascular coagulopathy are often the factors responsible for the death of neonates, who may concurrently have peritonitis diagnosed at surgery or at postmortem examination. For this reason, case-fatality rates often represent the mortality rate among newborns dying with, rather than because of, infection of the peritoneal cavity [230,236,243].

Before 1970, the incidence of fatalities was exceedingly high when peritonitis was associated with gastrointestinal perforation; mortality rates of 70% were observed in large series.* Heightened awareness of conditions associated with perforation, more rapid diagnosis, and improved

*References [190,231,234,235,237–239,244,280].

surgical management have led to a doubling of survivors in recent years [236,237]. The cause of perforation seems to influence the likelihood of survival, with spontaneous gastric perforation having the lowest mortality rate (10%) and perforation of the duodenum caused by a feeding tube the highest mortality rate (50%); NEC (40%) and all other causes (25%) occupy intermediate positions [243].

As survival rates have improved, the number of nonlethal complications after perforation has increased proportionally. In one review, two thirds of surviving infants had significant postoperative complications pertaining to infection (e.g., bacteremia, wound infection, intra-abdominal abscess) or gastrointestinal tract dysfunction (e.g., esophageal reflux, obstruction, stomal stenosis) [243]. Secondary surgical procedures to correct these problems were required in more than half of the infants. Parenteral hyperalimentation for nutritional support during the recovery period was required in 60% of infants.

The mortality rate among neonates with peritonitis from causes other than perforation of the bowel, such as sepsis [190,231,235,239], omphalitis [239,281], or a ruptured omphalocele [231,236,239], although high in the past, has not been reassessed in recent years [243]. Early diagnosis and institution of appropriate surgical therapy are major factors in reducing the mortality rate [243]. It has been shown that infants operated on within 24 hours after the onset of symptoms have survival rates almost double the rates of infants operated on between 24 and 48 hours and 2½ times higher than the rate for infants whose surgery was delayed more than 48 hours [244]. Factors with an apparent adverse influence on prognosis include low birth weight [231,236,239,243,261], low birth weight for gestational age [229], congenital malformations [236], male sex [230], and initial serum pH of less than 7.30 [230].

## TREATMENT

The treatment of bacterial peritonitis is directed primarily toward correction of the causative condition [230]. Careful attention to preoperative preparation of the infant is essential to survival. As soon as bowel obstruction or perforation is diagnosed, continuous nasogastric suction should be instituted for decompression and prevention of aspiration pneumonitis. Diagnostic needle paracentesis is also useful for relief of pneumoperitoneum and may facilitate exchange of gas by reducing the intra-abdominal pressure. Shock, dehydration, and electrolyte disturbances should be corrected through parenteral administration of appropriate electrolyte solutions, plasma, or plasma substitutes. If blood is discovered in fluid recovered by gastric suction or abdominal paracentesis, use of whole blood, packed red blood cells, or other fluids may be necessary to correct hypovolemia. Persistent bleeding must be evaluated for disseminated intravascular coagulation or thrombocytopenia, or both, and treated accordingly. Hypothermia, which frequently accompanies neonatal peritonitis, should be corrected before induction of anesthesia. Infants who are unable to tolerate oral or tube feedings within 2 or 3 postoperative days should be started on parenteral hyperalimentation.

If a diagnosis of peritonitis is established at the time of paracentesis or surgery, aerobic and anaerobic cultures of peritoneal contents should be taken before initiation of antibiotic therapy. Parenteral administration of a combination of gentamicin or an extended-spectrum cephalosporin and clindamycin and ampicillin should be continued for 7 to 10 days [215,228]. Other antibiotics that provide a broad spectrum against enteric organisms, *Pseudomonas* species, enterococci, and anaerobic organisms include β-lactam and β-lactamase inhibitor compounds and carbapenems. In the event of a poor clinical response, culture and susceptibility studies of the infecting organisms should be used as guides for modifying therapy.

Leakage of intestinal contents sometimes results in formation of a localized abscess, rather than contamination of the entire peritoneal cavity. Management of infants with such an abscess should include antimicrobial therapy and surgical drainage of the abscess by the most convenient route.

# NECROTIZING ENTEROCOLITIS

NEC with necrosis of the bowel wall is a severe, often fatal disease that has been occurring with increasing frequency in recent years. The average annual NEC mortality rate is 13.1 per 100,000 live births; black infants, particularly boys, are three times more likely to die of NEC than white infants, and mortality rates are highest in the southern United States [280,282–291]. NEC occurs in about 5% of infants admitted to NICUs; however, the incidence varies widely among centers and from year to year at the same institution [292–305]. NEC predominantly affects infants with birth weights less than 2000 g [282,284,298,213,306–312]; in several series, the frequency in infants weighing less than 1500 g was 10% to 15%.* Only 5% to 10% of all cases of classic NEC occur in term infants [291,318–320]. It has been stated that occasional cases of NEC may be the price to be paid for the benefits of modern neonatal intensive care [321].

Although most reports of NEC emanate from the United States, Canada, and Great Britain, the condition occurs worldwide in countries maintaining NICUs. In a review of NEC in two NICUs of academic centers, NEC increased the risk for death (odds ratio 24.5), infections (odds ratio 5.7), and need for central intravenous line placement (odds ratio 14.0) [322]. Infants with surgical and medical NEC had lengths of stay of 60 days and 22 days greater than infants without NEC with additional costs of $186,200 and $73,700, resulting in additional hospital charges of $216,666 per surviving infant.

NEC affects an estimated 7% to 14% of all low birth weight preterm infants [323] and is a leading cause of death and morbidity in the NICU with no change in incidence in the past 20 years [324,325]. More recent reports have estimated that about 9000 cases occur annually in the United States with a case-fatality rate of 15% to 30% [326].

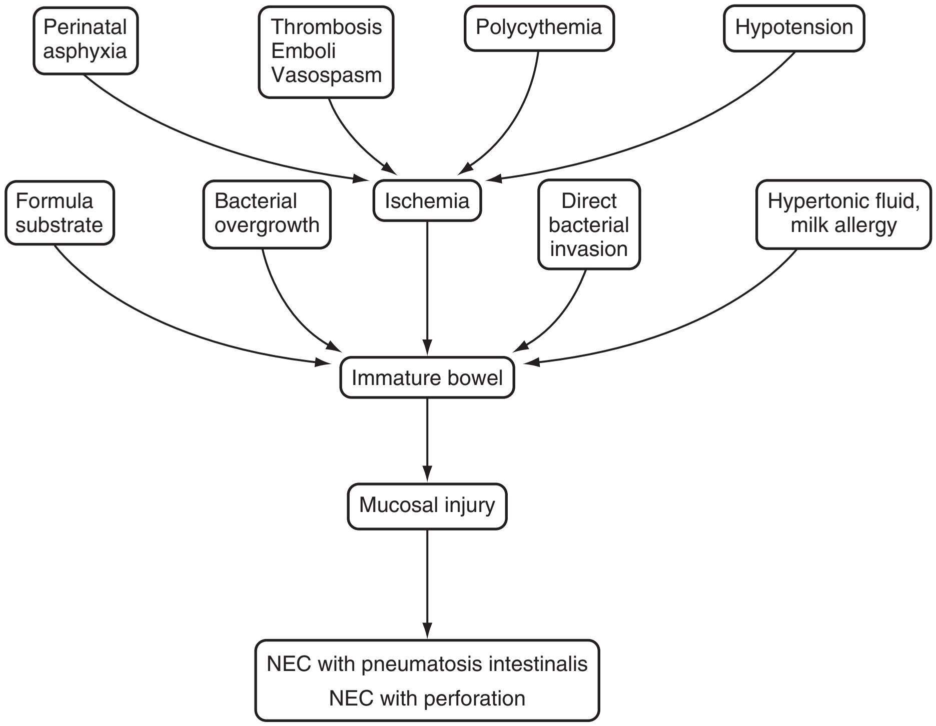

**FIGURE 10–3** Pathogenesis of mucosal injury leading to necrotizing enterocolitis (NEC). *(Adapted from Walsh MC, Kliegman RM. Necrotizing enterocolitis. Pediatric Basics 40:5, 1985.)*

## PATHOLOGY AND PATHOGENESIS

Bowel wall necrosis of variable length and depth is the characteristic feature of NEC, with perforation in one third of affected infants generally in the terminal ileum or cecum, where microcirculation is poor.* The pathogenesis of NEC is not established, but most investigators agree that the initiating event is some form of stress to the immature gastrointestinal tract, which leads to disruption of the mucosal barrier, bacterial invasion and proliferation, and gas formation within the bowel wall (Fig. 10–3) [213,298,306,330]. Surgical specimens from early stages of the disease show mucosal edema, hemorrhage, and superficial ulceration with very little inflammation or cellular response. By the 2nd or 3rd day, after progression to pneumatosis and transmural necrosis of the bowel wall, bacterial proliferation and the acute inflammatory reaction become more prominent [287,309].

There has been much investigation and little agreement on the importance of various perinatal events in the causation of NEC [213,298,306,331]. Except for immaturity and possibly polycythemia, other factors originally thought to predispose to NEC have been found on further study to occur with equal frequency in control populations of infants.* Maternal complications of pregnancy, labor, and delivery and neonatal respiratory distress syndrome are thought to be unrelated to the development of NEC, whereas evidence linking NEC to birth asphyxia, hypotension, hypothermia, use of vascular catheters, exchange transfusion, feeding history, abnormalities of gut motility, neonatal achlorhydria, and the presence of patent ductus arteriosus is often contradictory. Each of these conditions, singly or together, may act as a stress leading to mucosal injury, but none has been consistently associated with NEC [334,335]. NEC has occurred among apparently healthy infants with no known predisposing risk factors [282,280,318,330]. Several studies (discussed later) suggest that early feeding of premature neonates may play a causal role in NEC. Dvorak and coworkers [330] showed that maternal milk may be protective compared with artificial formulas in a neonatal rat model of NEC; similar to human NEC, artificial feeding of maternal milk reduced the incidence and severity of NEC injury, and IL-10 expression was significantly increased when neonates were fed maternal milk.

Some epidemiologic observations suggest that NEC is an infectious contagious disease of nosocomial origin. The temporal clustering of cases at institutions, the association of some outbreaks with single infectious agents or alterations in bowel flora, and the possible beneficial effects of breast-feeding, oral nonabsorbable antibiotics, or infection control measures in reducing the incidence of disease suggest a possible nosocomial cause. The evidence linking NEC to a specific infectious agent is often circumstantial or open to alternative interpretation. Evidence suggests that NEC is the end response of the immature gastrointestinal tract to multiple factors acting alone or in concert to produce mucosal injury, with colonization or invasion by the microorganisms representing only one part of the continuum of that disease process [266,272,273,280].

## MICROBIOLOGY

Descriptions of sporadic outbreaks of NEC in NICUs have led to a search for transmissible agents, including bacterial, viral, and fungal pathogens [341a].* Predominance

*References [243,287,280,309,318,327–329].

*References [213,299,304,310,311,320,332,333].

*References [288,298,306,213,330,336–341].

of a single organism in stool, blood, bowel wall, or peritoneal cavity of infants during epidemics of NEC has implicated numerous agents, including *Klebsiella* species [285,295,312,329,342–344], *Enterobacter* species [345], *E. coli* [346,347], *Pseudomonas* species [348,349], *Salmonella* species [350], *S. epidermidis* and other coagulase-negative staphylococci [351], *S. aureus* [352], rotavirus [353,354], coronavirus [355], coxsackievirus B2 [356], and *Torulopsis glabrata* [357].

The analogous pathology of necrotizing enteritis caused by *Clostridium septicum* [36,72] and *Clostridium perfringens* in domestic animals [297,344,358], older children, and adults [359] favored suggestions that *Clostridium* species might act as a primary pathogen in NEC.* Several reports provided evidence that *C. perfringens* [297,361–364], *Clostridium difficile* [333,365], or *Clostridium butyricum*, acting alone [366,367] or synergistically with *Klebsiella* [368], was able to evoke NEC. Subsequent studies indicated, however, that these species were often acquired from the nursery environment [369,370] and could frequently be recovered from healthy neonates [359,370–376]. Clostridial cytotoxin, which had been recovered from the stool of infants involved in an outbreak of NEC [333,365], has also been found in the stool of 90% of normal infants [333,364,369,375–377]. The role of *Clostridium* species in NEC remains unclear [341,360].

The δ-toxins, hemolysins of coagulase-negative staphylococci [378] and *S. aureus*, have also been proposed as possible primary toxins capable of producing NEC in infants. Frequent colonization by δ-toxin staphylococci and higher levels of toxin production by associated strains causing NEC [379] and one outbreak with δ-toxin–producing *S. aureus* strains have been reported [352]. Prospective studies have documented significant shifts in aerobic bacterial bowel flora within 72 hours before onset of clinical NEC [380]; the observed shift results from preclinical changes in the intestinal environment. This shift suggests that bacteria isolated at the time of onset were present because of possible intraluminal changes and are not directly involved in NEC.

Pending further experimental or epidemiologic observations, the weight of evidence indicates that although bacteria or bacterial toxins may play a primary or secondary role in the pathogenesis of NEC, the occasional association of this condition with a single organism probably reflects patterns of intestinal colonization prevalent in the nursery at the time of an outbreak [213,298,306,330]. Despite intensive efforts to identify a specific infectious agent or toxin in the cause of NEC, convincing reports implicating the same pathogen in more than one outbreak have not appeared [341].

## CLINICAL MANIFESTATIONS

Signs of NEC usually develop in the first 7 days of life [291,318,381], and 50% or more of cases are recognized within 5 days of birth [282,309,312,382,383]. Small immature newborns often develop illness later, during the 2nd to 8th week [314,316], whereas low-risk term infants may become ill shortly after delivery, as early as the first 24 hours [319].

NEC is a disease with a wide spectrum of manifestations, ranging from a mild gastrointestinal disturbance to a fulminant course characterized by early bowel perforation, peritonitis, sepsis, and shock [306,384,385]. A staging system (Table 10–4) taking these clinical variations into account may be useful in guiding patient evaluation and therapy [306,386]. The apparent stage of disease for an individual infant usually can be defined on the 2nd day of illness. An infant who exhibits only mild systemic and

**TABLE 10–4** Modified Bell Staging Criteria and Recommendations for Therapy for Necrotizing Enterocolitis

| | Signs | | | |
|---|---|---|---|---|
| **Stage** | **Systemic** | **Intestinal** | **Radiologic** | **Treatment** |
| IA (suspected) | Temperature instability, apnea, bradycardia, lethargy | Elevated residuals, mild abdominal distention, emesis guaiac-positive stools | Normal, mild ileus | NPO, antibiotics for 3 days |
| IB (suspected) | Same as IA | Frank rectal blood | Same as IA | Same as IA |
| IIA (definite), mild | Same as IA and IB | Same as IB plus absent bowel sounds ± abdominal tenderness | Dilation, ileus, pneumatosis intestinalis | NPO, antibiotics for 7-14 days if examination is normal in 24-48 hr |
| IIB (definite), moderate | Same as IIA with mild metabolic acidosis, mild thrombocytopenia | Same as IIA with definite abdominal tenderness ± abdominal cellulitis or right lower quadrant mass | Same as IIA plus portal gas ± ascites | NPO, antibiotics for 14 days |
| IIIA (advanced), bowel intact | Same as IIB plus hypotension, bradycardia, severe apnea, respiratory/ metabolic acidosis, disseminated intravascular coagulation, neutropenia | Same as IIB plus peritonitis, marked tenderness, abdominal distention | Same as IIB with ascites | Same as IIB plus 200 mL/kg fluid, inotropic agents, assisted ventilation, paracentesis |
| IIIB (advanced), bowel perforated | Same as IIIA | Same as IIIA | Same as IIIA plus pneumoperitoneum | Same as IIIA plus surgery |

intestinal signs 24 to 48 hours after onset is unlikely to develop a more serious illness [306].

The classic presentation of NEC includes a triad of abdominal distention, retention of gastric contents, and gastrointestinal bleeding.* These findings are often preceded or accompanied by signs consistent with sepsis, such as lethargy, poor feeding, temperature instability, apnea, and bradycardia. Diarrhea is variable, rarely observed in some series [306], but common in others [316,347]. Progression of bowel wall necrosis leading to perforation, peritonitis, and sepsis is reflected in deteriorating vital signs accompanied by persistent acidosis [387], clotting disorders, and circulatory collapse. Redness, induration, and edema of the anterior abdominal wall are commonly described in the advanced stages of NEC. In the absence of aggressive medical and surgical intervention, the course is rapidly downhill when late signs appear.

## DIAGNOSIS

Radiographic signs of NEC are largely nonspecific [385], and interobserver variability in the interpretation of films is substantial [387]. Radiographic examination of the abdomen remains the most reliable aid, however, in establishing a diagnosis of NEC [282,302,309,387,388]. Ileus with generalized bowel dilation and abdominal distention are the earliest radiologic findings. Increasing distention, separation of loops by peritoneal fluid or edema of the bowel wall, a gasless abdomen, pneumatosis intestinalis, and hepatic or portal air occur as NEC worsens. A persistent single dilated loop of bowel remaining relatively unchanged in shape and position in serial films is strongly suggestive [389–391] but not diagnostic [390,392] of localized bowel ischemia with impending perforation.

If free air or ascites is absent on initial abdominal examination, supine and left lateral decubitus films should be obtained every 6 to 8 hours until improvement or definitive surgery or invasive diagnostic measures have ruled out the presence of perforation. When perforation occurs, it is usually within 1 day after diagnosis [327], but may be delayed for 5 or 6 days [393]. Although the presence of pneumoperitoneum [244,265,275] or intraperitoneal fluid generally indicates perforation, its absence does not exclude perforation [221,243,244]. In one study [327], only 63% of infants with NEC and proven perforation had free air, 21% had ascites, and 16% had neither free air nor ascites.

When plain films are normal or equivocal, other studies may be diagnostic. A metrizamide gastrointestinal series may show intestinal perforation or abnormalities of the bowel wall, mucosa, or lumen [245,273,394]. Real-time ultrasonography may reveal portal venous and hepatic parenchymal gas in standard radiographs [327,395,396]. Serial abdominal transillumination with a fiberoptic light has been described as a bedside method for early detection of ascites or pneumoperitoneum, although its sensitivity compared with standard radiographic methods has not been determined [277].

A rapid and direct means of establishing the presence of intestinal necrosis or perforation is by abdominal paracentesis [269,397,398]. This procedure is unnecessary in infants to rule out NEC or in infants improving on medical therapy. The procedure is generally reserved for infants suspected, on the basis of clinical, radiographic, and laboratory findings, to have intestinal gangrene. When performed properly, paracentesis is safe and accurate, as described by Kosloske [399]: The abdomen is palpated to locate any masses or enlarged viscera. After an antiseptic skin preparation, a small needle (22-gauge or 25-gauge) is inserted carefully in the flank, at a 45-degree angle. It is advanced slowly and aspirated gently until free flow of 0.5 mL or more of peritoneal fluid is obtained. Any volume less than 0.5 mL is considered a dry tap and cannot be accurately interpreted. The color and appearance of the fluid are noted, and the fluid is transported immediately to the laboratory in an approved anaerobic container for Gram staining and for aerobic and anaerobic cultures. A positive paracentesis consists of brown fluid or bacteria on the unspun fluid.

The accuracy of paracentesis in determining the need for an operation is 90% to 95% [269,398]. False-positive results are rare; false-negative results are quite common. Patients with a dry tap should be closely observed under medical therapy with continuing serial paracenteses until indications for or against surgical intervention are clearly defined. Infants with a positive result should undergo exploratory surgery immediately.

Thrombocytopenia and disseminated intravascular coagulation are the most common hematologic complications [282,312,340,397,399–401], particularly in the presence of bowel gangrene or perforation [287,401,402]. Platelet-activating factor has been used to assist in the staging of NEC [403]; a cutoff level of 10.2 ng/mL had a positive predictive value of 100% in identifying infants with stage II or III NEC. Leukopenia and absolute granulocytopenia, apparently caused by margination of white blood cells rather than bone marrow depletion [404], also have occurred during early stages of the illness [399,400]. A low absolute granulocyte count persisting for 2 to 3 days is associated with a poor prognosis. Hemolytic anemia has been reported in association with NEC related to *C. perfringens* [363]. No consistent urinary abnormalities have been described for NEC, although increased lactate excretion, reflecting heightened enteric bacterial activity, may occur [405]. Increased amounts of fecal-reducing substances have been found in almost three fourths of formula-fed premature infants during early stages of NEC, before the onset of abdominal distention, poor feeding, or emesis [406]. Although not readily available, levels of growth factors in urine have been found to be much higher in children with stage II and III NEC [407]; such an analysis might identify children at higher risk of complications and the need for surgical intervention.

The evaluation of patients with NEC should include culture of blood and, when appropriate and clinically safe, cerebrospinal fluid, urine, and stool. The likelihood of bacteremia accompanying NEC depends on the severity of bowel involvement; the reported incidence has ranged from 10% to 67% among symptomatic infants. Combined data from several large studies showed positive blood cultures in about one third of newborns with NEC [287,288,339,393]. The usual organisms have been *E. coli*, *Klebsiella* species, *S. aureus*, and *Pseudomonas*

*References [292,303,316,318,320,329,337,342,391,396].

species, whereas enterococci and anaerobic bacteria were isolated occasionally. A spectrum of organisms similar to those causing sepsis have been isolated from the peritoneal fluid [287,295,316,340,393]. Meningitis may accompany bacteremia, occurring in approximately 1% of NEC cases [319,408].

## TREATMENT

Early and aggressive treatment must be initiated for any infant suspected to have NEC [298,306]. The modified Bell staging system of NEC may guide diagnostic studies, management, antibiotics, and surgical consultation and intervention (see Table 10–4). Umbilical catheters should be removed whenever possible, oral feedings should be stopped, and nasogastric tube drainage should be instituted. Fluid and electrolyte deficits and maintenance require rigorous attention; blood, plasma, or colloid infusions are often necessary for volume expansion and maintenance of tissue perfusion.

After appropriate cultures are obtained, parenteral antibiotic therapy should be started with clindamycin and gentamicin or an extended-spectrum cephalosporin and ampicillin. In nurseries where coagulase-negative staphylococcal colonization or infection is prevalent, initial therapy with vancomycin may replace ampicillin [409]. β-lactam and β-lactamase inhibitor combinations (e.g., piperacillin plus tazobactam) can replace gentamicin, ampicillin, and clindamycin, covering anaerobic, gram-negative enteric aerobic, and many gram-positive pathogens. Gentamicin and vancomycin dosages should be modified as necessary on the basis of serum levels. Despite anecdotal evidence that oral nonabsorbable aminoglycosides prevent gastrointestinal perforation in infants with NEC [410], later controlled studies did not corroborate this finding [411]; their use is not routinely recommended. The need for inclusion of clindamycin to provide activity against anaerobic bacteria in the management of NEC has been questioned [412], based on the observation that anaerobic bacteria are late bowel colonizers, present in relatively much lower numbers in infants than in adult subjects, and that anaerobes other than *Clostridium* species have been infrequently identified in NEC.

After immediate treatment has been started, follow-up studies should be instituted. These include serial examinations with measurement of abdominal girth; testing of stools for blood; levels of serum electrolytes, blood glucose, and arterial blood gases; complete blood cell count and platelet count; urine-specific gravity; and supine and left lateral decubitus abdominal radiographs. These tests should be considered every 6 to 8 hours until the infant's clinical condition stabilizes. Attention to vital functions should be provided as necessary on the basis of clinical, laboratory, or radiographic studies. Parenteral nutritional support through a central or peripheral vein must be started as soon as possible.

Early recognition and prompt initiation of medical therapy may reduce the need for surgery. Generally accepted criteria for surgical exploration are a deteriorating clinical condition despite appropriate medical therapy, signs of peritonitis, presence of free air within the abdomen, or a positive paracentesis result. The principles of surgical preparation and management have been discussed by several investigators [289,398,413,414]. In addition to laparotomy with removal of necrotic bowel, closed peritoneal drainage has been proposed as an alternative in very small infants, with a resultant survival of more than 50% [415].

## PREVENTION

The first observations implicating bacterial proliferation as a factor in pathogenesis of NEC prompted efforts at suppression of gut flora with topical antibiotics in the hope of preventing NEC. Attempts to prevent NEC by giving oral kanamycin or gentamicin prophylactically in the first hours of life, before any signs of bowel involvement are recognized, have generated contradictory data. In controlled clinical trials, a significant reduction in the incidence of NEC in treated premature infants was shown in some trials [313,416–419], whereas in others, investigators were unable to show any protective effect [419,420]. Studies of vancomycin [421] have shown a significant reduction in NEC in high-risk infants. Previous studies revealed selective growth of resistant organisms in bowel flora [313,420,422] and evidence of significant systemic absorption of aminoglycoside antibiotics [411,423,424], suggesting that oral aminoglycoside prophylaxis is not free of potential risks. Potential risk factors have not been examined in vancomycin trials, however. Until additional evidence is presented indicating clear-cut benefits from the use of oral aminoglycosides or vancomycin, it does not seem that either agent should be used routinely for prevention of NEC in premature infants. Epidemiologic evidence that early use of parenteral ampicillin and aminoglycoside therapy may delay or decrease the risk of NEC has not been confirmed in controlled studies [329].

Oral probiotics have been suggested to alter the bowel flora of the infant to reduce the incidence and severity of NEC. Infants fed breast milk and a product including *Lactobacillus acidophilus* and *Bifidobacterium infantis* had a reduced incidence and severity of NEC compared with infants fed breast milk alone [335]. A recent metanalysis of 11 trials of probiotics concluded that the risk for NEC and death was significantly lower, but the risk for sepsis did not differ significantly from those neonates not receiving probiotics [335a]. These results seem to confirm the significant benefits of or probiotic oral supplements, with a 30% reduction in the incidence of NEC.

Excessive or accelerated feedings have been associated with increased frequency of endemic NEC [425], and some clinicians have recommended a schedule of slow advancement of daily feeding volumes limited to about 20 mL/kg/day. Infants with NEC are more likely to have been fed earlier, to have received full-strength formulas sooner, and to have received larger feeding volumes and increments, and stress and associated respiratory problems may make such infants more vulnerable to NEC [244,292–297,426]. Prior studies of the use of a feeding regimen employing prolonged periods of bowel rest in high-risk infants showed the regimen to be successful in preventing NEC in some nurseries [298], but totally without value in others [213,300]. Later studies added additional support for standardized feeding schedules in low birth weight infants (500 to 2500 g); all used maximum volumes no greater than 20 mL/kg/day, with feeding

beginning at 24 to 72 hours after birth, depending on birth weight and gestational age [307,308]. Synthetic formulas and breast milk have been successful.

Carrion and Egan [427] suggested that relative hypochlorhydria of the neonate may contribute to NEC and found that hydrochloric acid supplements (0.01 to 0.02 1.0 N HCl/mL of formula) significantly reduced NEC rates and lowered gastric pH. Additional studies have shown that standardized feedings begun at a median of 4 days after onset of NEC can be associated with an abbreviated time until institution of full enteral feedings, a reduced incidence of the use of central catheters and catheter infections, and ultimately a shorter hospital stay [428].

Many NEC "epidemics" in NICUs, lasting 2 weeks to 7 months, have been reported from centers worldwide [329,340,341,429,430]. Although the microbiologic agents associated with these outbreaks have varied, institution of strict infection control measures was often useful in bringing about a significant decrease in the incidence of NEC; the reasons for success are less clear. Results have been sufficiently impressive, however, to recommend that enforcement of bedside enteric precautions, together with cohorting of infants and staff, be instituted when two or more cases of NEC occur in a nursery [306,341,431].

The use of human breast milk has been claimed, largely on the basis of experimental evidence, to exert a protective effect against the development of NEC. There are no prospective, controlled studies showing any benefit from the feeding of colostrum or breast milk to human neonates. A study showing the protective effect of an orally administered IgA-IgG preparation suggests a possible way to provide benefits of high levels of functionally active antibodies in the gastrointestinal tract [432]. Orally administered probiotics have been suggested as a possible prophylactic measure in NEC based on an assumption that an accentuated and inappropriate inflammatory response to colonizing pathogenic flora in the premature gut plays a role in the initiation of NEC [433]. Bifidobacteria and lactobacilli are commonly found in breast-fed infants [434] and may be the reason in part for the protective effects of breast milk. A single large, multicenter, randomized controlled trial of *Bifidobacterium bifidum* and *L. acidophilus* was completed and suggested a lower incidence of NEC (stage II or greater) in infants receiving these probiotics [435]. This study showed a lower incidence of death or NEC in recipients of probiotics (4 of 217 probiotic infants versus 20/217 control infants). No adverse effects of the probiotics, such as sepsis, flatulence, or diarrhea, were noted. This large study seems to confirm several smaller studies with similar results [436,437,438].

## PROGNOSIS

The mortality rate of NEC is difficult to determine because mild cases of suspected NEC are probably more common than is recognized [306,376,439]. In studies in which analysis has been limited to infants with "definite NEC," mortality figures range from 20% to 40%.* Several longitudinal studies have shown a significant improvement in outcome [291,302,387,440]. A poor prognosis has been linked with very low birth weight, associated congenital defects, bacterial sepsis, disseminated intravascular coagulation, intestinal perforation, and persistent hemodynamic or respiratory instability [311,336,381,393]. Surgical intervention, generally reserved for the sickest infants with more extensive bowel involvement, is also associated with higher mortality rates [311,381,387,398,439].

Infants who survive the acute phase of illness generally do well, although NEC may recur in 5% to 10% [291,316,440,441]. In addition to surgical complications (e.g., short bowel syndrome, anastomotic leaks, fistula formation), enteric strictures are probably the most common delayed complication in surviving infants, occurring in 4% to 20%. Usually found at sites of ischemia and necrosis in terminal ileum or colon [282,309,442], these strictures often become apparent within a few weeks, but may be delayed 18 months. When multiple strictures occur, the intervening normal bowel may form an enterocyst [388,443]. Clinically, strictures manifest as frequent episodes of abdominal distention, often with vomiting, obstipation, or hematochezia. Diagnosis is confirmed by gastrointestinal contrast studies. Surgery with removal of the stenotic site is necessary to effect a cure.

Long-term follow-up of low birth weight infants with severe NEC (i.e., Bell stages II and III) has documented higher rates of subnormal body weight (15% to 39%) and head circumference (30%) in addition to significant neurodevelopmental impairment (83%) [444]. Clinical observations suggest that infants with bowel resection for NEC are at increased risk of sepsis, occurring 1 week to 3 years (mean 4 months) later. Almost all had had a central venous catheter in place for parenteral nutrition at the time of infection. Enteric bacilli were responsible for more than 40% of bacteremias, whereas only 20% were caused by staphylococcal species, which are the usual causes of catheter sepsis. Several infants had two or more episodes of sepsis, and 2 of 19 died as a direct consequence of infection [427].

## ENDOCARDITIS

Neonatal bacterial endocarditis, previously uncommon, has been recognized more frequently in recent years. About 60 cases that meet clinical and bacteriologic criteria sufficient to establish this diagnosis were reported in the literature before the mid-1980s [77,445–472]. The prolonged survival of critically ill infants, including infants with complex congenital heart disease, and the increased use of intravascular catheters, together with advances in the diagnostic sensitivity and availability of echocardiography, may be responsible for an increased recognition of endocarditis. In a 35-year review of 76 cases of endocarditis in children, 10% of patients were younger than 1 year; the youngest patient was 1 month old [473]. Of patients, 62 (83%) had congenital heart disease, and 77% had had prior surgery. Central venous catheters were additional significant risk factors. At the University of New Mexico in a level III nursery with 3200 to 3500 admissions annually, 12 cases of endocarditis occurred in children younger than 3 months [474]. Organisms isolated from these 10 cases included *S. aureus* (6 cases), *K. pneumoniae* (1 case), *Enterobacter cloacae* (2 cases),

*References [269,291,298,213,316–320,381,385,387].

*Candida* species (1 case), α-hemolytic streptococci (1 case), and coagulase-negative staphylococci (1 case). Three patients had congenital heart disease with early surgical intervention; all had surgically implanted catheters or intravenous access devices, one had NEC, and one had an associated osteomyelitis.

Etiologic agents of bacterial endocarditis in newborns have been identified by isolation from blood cultures or morphologic characteristics of organisms entrapped within valvular vegetations examined at autopsy. The causative organisms have included *S. aureus* in 36 infants*; streptococci in 6 infants [425,447,475]; *S. epidermidis* [455,456,476] and GBS [449,459,463] each in 5 infants; *S. pneumoniae* [447,475], *P. aeruginosa* [448,454], and *S. marcescens* [452,464] each in 2 infants; and *Neisseria gonorrhoeae* [447], *S. faecalis* [477], *Streptococcus salivarius* [71], and mixed α-hemolytic streptococcus, *K. pneumoniae*, and *P. mirabilis* [455] each in 1 infant. Despite widespread cardiovascular involvement associated with congenital syphilis, there is no conclusive evidence that this disease produces valvular heart lesions in infected infants [58]. *Candida* endocarditis has become increasingly prevalent, particularly associated with the use of central venous catheters.

Factors that predispose a newborn to endocarditis are not well understood, although intravascular catheters are associated with endocarditis. In contrast to older children, in whom congenital heart disease is often associated with endocarditis [478], cardiac anomalies were found in only nine of the reported cases in neonates in series before 1994.* Bacteremia arising from an infected umbilical stump [446–448], conjunctivitis [447], and skin lesions [447,469] were the presumed sources of valvular involvement in six infants; the invasive organisms associated with these conditions and with neonatal endocarditis in general can infect normal heart valves [480]. Nevertheless, the greater frequency of bacterial and fungal [468,481–488] endocarditis in newborns in recent years, particularly in association with prematurity or placement of central vessel catheters, or both, indicates that other, more complex mechanisms may also be operative in some cases [454–457,471,476,481,489].

Observations in laboratory animals and autopsy studies of adults have shown that damage to the intracardiac endothelium with formation of a sterile platelet-fibrin thrombus at the site of the injury is often the initiating event in a patient with endocarditis [486]. Endocardial trauma caused by placement of cardiac catheters, disseminated intravascular coagulation, and various nonspecific stresses associated with prematurity, such as hypotension and hypoxia, has been implicated in the genesis of thrombi.* Nonbacterial thrombotic endocarditis or verrucous endocarditis usually remains uninfected and is described as an incidental finding at autopsy [454,471,491,492]. With bacteremia, implantation of organisms may lead to valvular infection. Whether this mechanism or direct bacterial invasion is primarily responsible for valvulitis is unknown. A similar pathogenesis has been postulated for formation of mycotic aortic aneurysms in newborns [467,493,494].

*References [455–457,460,463–465,467,468,475–487,489–510].

*References [77,450,452,455,459,460,465,479].

*References [455,471,476,480,490,491].

Endocarditis should be suspected in any neonate, particularly a premature infant, with an indwelling vascular catheter, evidence of sepsis, and new or changing heart murmurs. When these findings are accompanied by persistent bacteremia or signs of congestive heart failure in the absence of underlying heart disease, the diagnosis must be considered seriously. Although Janeway lesions [471], a generalized petechial rash [466,477,481], and splinter hemorrhages [477] have been seen, murmurs characteristic of semilunar valve insufficiency, Osler nodes, Roth spots, arthritis, and other findings typical of valvular infection in adults and older children have not been observed in neonates. Multiple septic emboli with involvement of the skin, bones, viscera, and central nervous system are common findings, however.*

Two-dimensional echocardiography has proved to be an invaluable rapid, noninvasive method for diagnosing endocarditis [456–459,465,486,495]. Although it cannot differentiate between infected and sterile vegetations and other valvular lesions (discussed later), imaging is quite specific, and false-positive readings are uncommon. Less certainty can be placed on a negative report. Despite detection of vegetations 2 mm in diameter with echocardiography, the number of false-negative examinations is significant [465,471,496]; in one series, two of three infants with thrombotic valvular lesions 3 to 7 mm in diameter had normal two-dimensional echocardiograms [471]. A diagnosis of bacterial endocarditis should be considered in any infant with a compatible history and physical findings regardless of the results obtained by echocardiography. Widespread use of new techniques, such as transesophageal echocardiography, which provides detailed views of the mitral and tricuspid valves, and color flow Doppler imaging, which can identify areas of turbulence as blood passes over vegetations or through narrowed valve leaflets, may greatly improve diagnostic accuracy in the future [495].

When endocarditis is suspected, specimens of blood, cerebrospinal fluid, and urine obtained by catheterization or suprapubic aspiration should be sent for bacterial and fungal culture. Because blood drawn from a central catheter often contains organisms colonizing the line but not present in the systemic circulation, at least two peripheral venous blood cultures should be obtained before antimicrobial therapy is initiated. Volumes of 1 to 5 mL, depending on the infant's size, should be adequate [486].

Routine laboratory studies are helpful in supporting a diagnosis of endocarditis in the newborn. The leukocyte count, differential count, and platelet count are usually indicative of sepsis, rather than cardiac valve infection in particular. Microhematuria has been reported, although rarely [471,477]. A chest radiograph should be obtained to determine signs of cardiac failure or pulmonary or pleural space infection. CT or MRI of the brain can be helpful in an infant with neurologic signs, particularly if left-sided endocarditis or a right-to-left shunt exists. Baseline determinations of inflammatory markers are useful and can be used for assessing the efficacy of the therapy; erythrocyte sedimentation rate and C-reactive protein level have been used.

*References [455,457,459,460,464–466,468–474,478,479,481,485,487,489,508–510].

Intravenous therapy with a penicillinase-resistant penicillin and an aminoglycoside should be started after appropriate cultures have been obtained. In nurseries where MRSA or methicillin-resistant *S. epidermidis* infections have been a problem, vancomycin should be substituted initially for the penicillin antibiotic [486,495,496]. If endocarditis caused by *Enterococcus* species is suspected, ampicillin should be added or substituted for the penicillinase-resistant penicillin. After the infecting organism is isolated and antibiotic susceptibilities have been determined, specific antimicrobial therapy can be instituted.

Four to 8 weeks of parenteral treatment is usually adequate, depending on the susceptibility of the organism, response to therapy assessed clinically by reduction or elimination of the observed vegetations, and laboratory response. C-reactive protein level often normalizes 2 to 3 weeks before erythrocyte sedimentation rate, and blood cultures are usually sterile after 3 to 5 days of effective therapy. *Candida* species may persist for weeks, however, despite the use of active antifungal drugs. Dosage and efficacy should be monitored weekly with clinical and bacteriologic response with or without serum antibiotic and bactericidal levels [495,497]. Determination of serum bactericidal titers (Schlichter test) is of uncertain value and has never been validated in neonatal endocarditis [486,495,498]. Efficacy of treatment may also be monitored with serial echocardiograms taken until vegetations remain stable in size or disappear [465,466,468,476,481].

Intravascular catheters must be removed whenever possible, and the tip of the removed catheter should be cultured [486,499]. Extremely large or mobile vegetations occluding an outflow tract or posing a high risk of embolism may have to be removed surgically [463,465,468]. In infants with right-sided endocarditis, demonstration of decreased pulmonary blood flow through the use of ventilation-perfusion scan can be valuable in confirming the presence of emboli, particularly if there is clinical evidence of increasing respiratory effort and diminished peripheral oxygen saturation [463].

With the availability of echocardiography, improved clinical awareness, and early diagnosis, prognosis has improved. Although there were infrequent survivors before 1973 [480], the first survivors with proven endocarditis were reported in 1983 [465,466,471]. Approximately two thirds of subsequent cases have been cured. Death is usually the result of overwhelming sepsis, often in conjunction with cardiac failure. Early reconstructive surgery for infants who fail medical management may be helpful, but has been reported in only a few cases [500,501].

Inspection of the heart at autopsy has shown the mitral valve to be infected, alone or in combination with other valves, in about half of patients. The tricuspid valve was involved in 12 infants, the pulmonary valve in 7, the aortic valve in 6, infected mural thrombi in 12, and an unspecified site in 3. Microscopic examination of valve cusps has revealed the characteristic lesions of endocarditis, with multiple small, confluent, friable vegetations composed principally of bacteria and thrombi surrounded by inflammatory exudate [77,469,471]. On gross inspection, these vegetations are easily confused with noninflammatory lesions, such as those of nonbacterial thrombotic endocarditis, blood cysts [502], developmental valvular defects [503], or hemangiomas or other vascular anomalies [504]. Cases described as fetal endocarditis in the literature are almost certainly examples of these types of lesions [503,505,506].

## PERICARDITIS

Purulent pericarditis is a very unusual complication of neonatal sepsis. Approximately 20 cases of proven bacterial origin have been reported within the past 50 years [18,507–518]. No single causative agent has predominated. *S. aureus* was responsible for seven cases [18,507–509]; *E. coli* was isolated from three patients [509, 514,515]; *Haemophilus influenzae* was found in two cases [510,517]; and *Salmonella wichita* [511], *Klebsiella* [518], and *P. aeruginosa* [516] were isolated from single cases. One early review of *Pseudomonas* sepsis described suppurative pericarditis in four neonates [512]. Another report on the recovery of *Pseudomonas* from the pericardium of premature infants dying of septicemia and meningitis during a nursery outbreak is difficult to evaluate because details of clinical and autopsy findings were not provided [519]. Cases caused by *Candida* species and *Mycoplasma hominis* have also been described [481,485,520]. The causes of a pericardial effusion in three fetuses with multiple congenital anomalies, myocardial hypertrophy, and pericarditis are uncertain. Although the inflammatory exudate found at autopsy contained polymorphonuclear leukocytes in addition to lymphocytes, no evidence of bacterial infection was found [521].

Virtually every infant with pericarditis has associated septic foci; pneumonia and multiple pulmonary abscesses are the most common sites. Involvement of pericardium may occur by direct extension from adjoining lung abscesses or by hematogenous spread of bacteria [508]. The presence of infectious processes elsewhere is sufficiently frequent to warrant the suggestion that pericarditis should be suspected in all infants who develop clinical signs of "heart failure" or a sudden increase in the size of the cardiac silhouette during the course of a purulent infection such as meningitis, pneumonia, or omphalitis [510,522].

Neonates with bacterial pericarditis generally present with signs and symptoms suggesting sepsis and respiratory distress. Poor feeding, listlessness, emesis, or abdominal distention may be seen in the presence of tachypnea, tachycardia, and cyanosis of various degrees. More specific signs of cardiac involvement become apparent with the accumulation of increasing amounts of pericardial effusion. The clinical findings of cardiac tamponade are extremely subtle and difficult to differentiate from the findings of myocardial disease with right-sided heart failure. A rapid pulse, quiet precordium, muffled heart sounds, neck vein distention, and hepatomegaly are findings common to both entities. More specific signs of tamponade, such as narrow pulse pressure or respiratory variations in pulse volume of more than 20 mm Hg (i.e., pulsus paradoxus), are technically difficult to obtain in neonates without an arterial catheter in place. A pericardial friction rub is absent in more than 50% of older infants and children and in most neonates with purulent pericarditis.

Rapid enlargement of the cardiac silhouette, a globular heart shape with widening of the base on tilting, and

diminished cardiac pulsation on fluoroscopic examination are of little value in differentiating pericardial effusion from cardiac dilation [523]. The early ST segment elevation and subsequent T wave inversion seen on electrocardiogram reflect subepicardial damage or inflammation and are similar to changes seen with primary myocarditis. Diminution in the amplitude of the QRS complex by fluid surrounding the heart is not a constant finding. Confirmation of the presence of a pericardial effusion is usually obtained by two-dimensional echocardiography [507,523]. In some cases, CT or MRI can also be helpful in delineating the extent of a pericardial effusion [524]; occasionally, pericardial fluid is found incidental to the chest or abdominal scanning. Additional causes of neonatal pericardial effusion other than purulent disease include viral pericarditis [525], intrapericardial teratoma [526], maternal lupus [527], immune and nonimmune [528] fetal hydrops, congenital diaphragmatic defects [529], chylopericardium [530], and central venous catheter perforation of the right atrium [531].

A definitive diagnosis of purulent pericarditis can be made only by obtaining fluid at surgery or through needle aspiration. Care and experience are necessary to facilitate aspiration while avoiding the risks of cardiac puncture or laceration [521]. Accurate monitoring of needle position can usually be obtained through CT guidance, with echocardiographic or fluoroscopic imaging, or by attaching the exploring electrode (V lead) of an electrocardiograph to the needle and by looking for injury current if contact is made with the epicardial surface of the heart.

When fluid is obtained, it should be sent for analysis to the laboratory in a laboratory-approved container appropriate for aerobic and anaerobic culture, mycobacteria, and fungi. In addition to cell count and protein and glucose levels, Gram and acid-fast stains should be performed with cultures for bacteria, viruses, mycobacteria, and fungi. Rapid identification of bacterial antigens by latex agglutination or by counterimmunoelectrophoresis of pericardial fluid, urine, or serum may also help to establish an etiologic diagnosis [532]. Specialized testing for rare bacterial, viral, or fungal organisms by molecular methods may be available by request in specialized (research) or reference laboratories.

Purulent pericarditis is a medical and surgical emergency. Therapy must be directed toward relief of the cardiac tamponade through adequate pericardial drainage and toward resolution of the infection. Both modes of treatment are essential for successful therapy for bacterial pericarditis in the newborn. No infant with suppurative pericarditis has recovered when treated by antibiotics alone [508]. Although repeated needle aspirations or catheter drainage [533] may be sufficient, the frequent occurrence of loculations of pus, particularly with staphylococcal infection, suggests that open surgical pericardiostomy is the method of choice to achieve adequate drainage.

Cultures of blood, and, when clinically indicated, cerebrospinal fluid and urine should be obtained before instituting antimicrobial therapy. Initial therapy should be based on results of Gram stain or antigen detection tests of the pericardial fluid. If no organisms can be identified, treatment can be started with penicillinase-resistant penicillin and an aminoglycoside (or extended-spectrum cephalosporin) until definitive culture and susceptibility data are available. In nurseries where MRSA infection has been a problem, vancomycin should be substituted for penicillin [497].

The prognosis of neonatal purulent pericarditis is very poor. Only three survivors had been reported [507,509,518] before the 1990s. Treatment of these patients consisted of needle aspirations, drainage, and systemic antibiotic therapy, and in one case, treatment was combined with local instillation.

## MEDIASTINITIS

Purulent mediastinitis has been reported in 11 infants younger than 6 weeks of age, although it is likely that a great many more cases occur than have been reported in the literature, and that it is an occasional complication of cardiothoracic surgery performed in the neonatal period. Six reported patients acquired mediastinal abscess through blood-borne dissemination of organisms [534–536] or by extension from a focus of infection in an adjacent retropharyngeal abscess [537], pleural or pulmonary abscess [508,535], or vertebral osteomyelitis [538]. One infant developed infection as a complication of surgery for esophageal atresia [525]. *S. aureus* was the causative organism in four infants, and *S. pneumoniae*, *Clostridium* species, and mixed *S. aureus* and *E. coli* were causative in one infant each. Organisms were not identified in four cases.

Traumatic perforation of the posterior pharynx or esophagus, often the result of resuscitative efforts in infants involving endotracheal or gastric intubation, produces a potential site for entry of microorganisms [539–546]. Retropharyngeal abscess [547], an infected pseudodiverticulum, or pyopneumothorax may occur as a consequence; purulent mediastinitis has been reported three times as a complication [536,540,541], but it is probably more common than is reported. At least one case of mediastinitis has occurred as the result of overly vigorous passage of a nasogastric tube through an atretic esophageal pouch [540]. Low (intrathoracic) perforations are said to have a higher risk of mediastinitis and abscess formation than perforations in the cervical region [542].

Early symptoms are nonspecific and are similar to symptoms of any septic process in a neonate. As purulent fluid accumulates in the mediastinum, it places increasing pressure on the esophagus, trachea, and tributaries of the superior vena cava and thoracic duct, bringing about rapid development of dysphagia, dyspnea, neck vein distention, and facial cyanosis or edema. To maintain a patent tracheal airway, an affected infant lies in an arched position with head extended in a manner very similar to that seen in neonates with congenital vascular ring. A halting, inspiratory, staccato type of breathing, probably because of pain, is also characteristic. Ultimately, the abscess may point on the anterior chest wall or in the suprasternal notch.

Usually, mediastinitis is first suspected when widening of the mediastinum is observed on a chest radiograph obtained for evaluation of respiratory distress. Forward displacement of the trachea and larynx may accompany these findings when retropharyngeal abscess is associated with mediastinitis. Infection after traumatic perforation of the esophagus or

pharynx is often accompanied by pneumomediastinum with or without a pneumothorax [540,542].

Contrast studies performed to define the cause of respiratory or feeding difficulties in infants with mediastinitis may result in flow of radiopaque fluid into an esophageal laceration, mimicking the findings of an atresia, duplication, or diverticulum of the esophagus [542,543]. In such cases, endoscopy often shows a mucosal tear, confirming the diagnosis [543,544].

Treatment should be directed toward establishment of drainage and relief of pressure on vital structures through a mediastinotomy and placement of drainage tubes. A tracheostomy or endotracheal tube may be necessary for maintenance of an adequate airway. Initial empirical antimicrobial therapy with clindamycin (or metronidazole), ampicillin, and an aminoglycoside (or extended-spectrum cephalosporin) and β-lactam and β-lactamase inhibitor combination should be started after cultures of the blood and all other clinically indicated cultures have been obtained. More limited empirical antibiotic therapy can be provided with a β-lactam and β-lactamase inhibitor combination alone, such as piperacillin plus tazobactam, ampicillin plus sulbactam, or ticarcillin plus clavulanate. Specific therapy can subsequently be determined by the results of bacteriologic studies of the cultures or purulent fluid obtained at surgery.

## ESOPHAGITIS

The esophagus is infrequently a focus for infection of the fetus or newborn [548]. Esophageal atresia is associated with congenital rubella (see Chapter 28). Severe esophagitis has also been reported in neonates with congenital cytomegalovirus infection [549]. The esophagus may be involved in infants with congenital Chagas disease, identified by signs of dysphagia, regurgitation, and megaesophagus [550]. Esophageal disease may follow mediastinitis in the neonate (discussed earlier). Only occasional cases of bacterial esophagitis in a neonate have been reported; a 940-g infant boy developed signs of sepsis on the 5th day of life and died 5 hours later [551]. Premortem blood cultures were positive for *Bacillus* species. Examination at autopsy revealed histologic evidence of esophagitis with pseudomembranous necrosis of squamous epithelium and many gram-positive bacilli. No other focus of infection was evident.

## INFECTIONS OF ENDOCRINE ORGANS

Endocrine glands other than the adrenal are rarely involved in fetal or neonatal infection. Nelson [552] reported neonatal suppurative thyroiditis in a term Laotian infant. The infant presented with a left anterior neck mass at 3 days of age. At surgery, a cystic mass within the left lobe of the thyroid was identified. Purulent material within the mass grew viridans streptococci and nonhemolytic streptococci.

Orchitis caused by *S. enteritidis* was described in a 10-week-old neonate [553]. The infant presented with symptoms of sepsis and diarrhea, subsequently developing unilateral scrotal swelling and erythema on the 5th day after onset of illness. Ultrasound examination of the testis showed a patchy increased echo intensity; the diagnosis was confirmed at exploratory surgery to rule out testicular torsion. Three other cases of infection of the testes caused by *Salmonella* species in infants younger than 3 months have been described [552].

## INFECTIONS OF THE SALIVARY GLANDS

Neonatal infections of salivary glands are uncommon; although rare, involvement of the parotid is the most frequent [554–559], and submandibular gland infection is infrequent [554–556]. Most infections are caused by *S. aureus* [553–556], but *E. coli* [556], *P. aeruginosa* [556], and GBS (see Chapter 12) have also been implicated in suppurative parotitis. Oral anaerobic bacteria, including *Bacteroides* species and *Peptostreptococcus* species, may be found in mixed or isolated infections in more than half of cases [557]. Infections of the salivary glands occur more frequently in premature and male infants [556,559] and most commonly manifest during the 2nd week of life. The oral cavity is the probable portal of entry for the infecting organism. Blood-borne bacteria may invade the salivary glands, however. Dehydration with resultant decreased salivary flow may be a predisposing cause in some infants.

The clinical manifestations of salivary gland infection include fever, anorexia, irritability, and failure to gain weight. There may be swelling, tenderness, or erythema over the involved gland. Purulent material may be expressed from the ductal opening with or without gentle pressure over the gland.

The diagnosis is made by culture, Gram stain, or both of the pus exuding from the duct or by percutaneous aspiration of a fluctuant area. If microscopic examination of the Gram stain does not suggest a responsible pathogen, initial antibiotic therapy should be directed against *S. aureus*, *E. coli*, and *P. aeruginosa* (i.e., penicillinase-resistant penicillin or vancomycin plus an aminoglycoside or extended-spectrum cephalosporin with activity against *Pseudomonas* organisms). If there is a strong suspicion of involvement with anaerobic bacteria (i.e., negative aerobic cultures or failure to respond to therapy directed at aerobic pathogens), consideration should be given to adding or substituting antibiotics appropriate for anaerobic bacteria (e.g., clindamycin, metronidazole in combination with other antibiotics, or a β-lactam and β-lactamase antibiotic alone). The duration of therapy should extend throughout the period of inflammation and 3 to 5 days after signs of local inflammation have disappeared. Incision and drainage often may be required; surgical drainage should be considered if there is not a prompt response to therapy within 72 hours or if the gland becomes fluctuant. When considering incision and drainage, careful attention to preservation of the function of overlying motor branches of cranial nerve VII is important.

## INFECTIONS OF THE SKIN AND SUBCUTANEOUS TISSUE

Bacterial infections of the skin of the newborn may manifest as maculopapular rash, vesicles, pustules, bullae, abscesses, cellulitis, impetigo, erythema multiforme, and petechiae or purpura. In a review of 2836 neonatal

infections in Finland, only 6 were characterized as cellulitis [561]. Most infections of skin are caused by *S. aureus*, including bullous impetigo, chronic furunculosis, scalded skin syndrome, and breast abscesses (see Chapter 14). Cellulitis frequently accompanied by adenitis and bacteremia may be caused by GBS (see Chapter 12). Cutaneous infections caused by many other bacteria are discussed in this section; however, most microorganisms that cause disease in the neonate may produce cutaneous infections, and those infections are discussed in other chapters when relevant. For additional information on bacterial infections of the skin, the reader is referred to the text by Solomon and Esterly [562] and the reviews by Swartz and Weinberg [563] and Frieden [568]. Excellent color photographs are included in the *Color Atlas of Pediatric Dermatology* by Weinberg and coworkers [569].

Methicillin (oxacillin)-resistant (i.e., MRSA) infection is responsible for about 50% of cutaneous infections and is the frequent portal of entry for cutaneous infections in neonates [564]. MRSA cutaneous infections have included cellulitis and abscess formation, but may progress more frequently and rapidly to septicemia and disseminated infections to involve bones, joints, lung, central nervous system, and the cardiac endothelium [565]. In a 4-year survey (2001-2005) of staphylococcal infections in one center, 89 neonates were infected with staphylococci, and 61 (68.5%) infections were caused by MRSA; 30% of MRSA and methicillin-susceptible *S. aureus* infections manifested with pustular lesions, most often in the groin [566]. Cellulitis or abscess developed with 20% of MRSA and 32% of methicillin-susceptible *S. aureus* lesions, and 13% of lesions developed into an invasive infection (bacteremia, urinary tract infection). Also, infants with MRSA were more likely to have a mother with a history of skin infection (21% versus 4%). Other investigators have attempted to eradicate high colonization and disease rates in neonatal nurseries with the use of bacteriostatic agents applied to the umbilical cord. In one study with a high rate of MRSA impetigo, 0.3% triclosan (Bacti-Stat) was not effective in slowing the progress of the epidemic [567]. In this epidemic, 22 infants were affected, and all but 2 of the affected infants were circumcised, suggesting that the colonization of the surgical site facilitated invasion of the skin.

## PATHOGENESIS

The skin of the newborn has unique characteristics, including absent microflora at birth; the presence of vernix caseosa; a less acid pH than that of older children; and often the presence of surgical wounds, including the severed umbilical cord, a circumcision site, and catheter wounds. The infant is immediately exposed to other infants, personnel, and the nosocomial environment. After the staphylococcal pandemic of the 1950s, information on the colonization of the skin, predisposing factors responsible for neonatal skin infection, bacterial transmission in the nursery, the inflammatory response of the skin to bacterial invasion, virulence factors of staphylococci, and methods of prevention of cross-infection became available. These studies are described in part in Chapters 14 and 35 and have been reviewed elsewhere [568,569].

Cutaneous bacterial infection may be a primary event or the result of systemic infection [570]. Septicemic embolic infection may occur at widely separated sites, whereas local infections often occur at a site with an identifiable predisposing cause. Procedures resulting in breaks in the cutaneous continuity, such as forceps abrasions or wounds at fetal electrodes or at venipuncture sites, may be readily identified. The necrotic umbilical cord is a site for proliferation of microorganisms that may invade local tissues.

Infection of the circumcision site remains a concern because it is the most common surgical procedure in infants in the United States. Speert [571] found that cleanliness was frequently disregarded by professional circumcisers in the 19th century. Operators were frequently uneducated, were dirty, and often spat on their instruments. Erysipelas, tetanus, and diphtheria have long been recognized as complications of unsterile surgical technique performed on newborns. In a now obsolete and prohibited part of the Orthodox Jewish circumcision ritual, the operator applied his lips to the fresh circumcision wound and sucked a few drops of blood. Such practices were responsible for transmission of syphilis and tuberculosis in neonates in the past. In one report [570], a 4-month-old infant presented with a penile ulcer, bilateral inguinal adenopathy, and a draining inguinal sinus caused by *Mycobacterium tuberculosis* after the “barber” spat on his razor before circumcision. Reports of 43 cases of tuberculosis associated with circumcision had been published by 1916 [569].

Subsequent case reports of severe infection after circumcision include bacteremia related to GBS [571], local infection and fatal staphylococcal pneumonia [572], staphylococcal scalded skin syndrome [573,574], necrotizing fasciitis [575], and bullous impetigo [576]. Two reports of necrotizing fasciitis after Plastibell circumcision emphasize severe infection as a potential risk of this procedure [577]. One infection caused by *S. aureus* and *Klebsiella* species was associated with prolonged convalescent and multiple surgical repairs, whereas a second infant survived staphylococcal necrotizing fasciitis after 14 days of intravenous antibiotic treatment.

The incidence of infection after elective circumcision was investigated at the University of Washington Hospital [578] from 1963-1972. Infection, defined as the presence of pus or erythema, occurred in 0.41% of 5521 infants and was more frequently associated with the use of a disposable plastic bell (Plastibell, 0.72%) than with the use of a metal clamp (Gomco, 0.14%). Wound cultures were infrequently available, and the microbiologic diagnosis was uncertain for most infants. Circumcision infection is uncommon, but local spread of infection may be devastating and lead to systemic infection.

Intrapartum fetal monitoring with scalp electrodes and intrauterine pressure catheters and measurements of fetal blood gases through scalp punctures have been associated with infections related to herpesvirus (see Chapter 26), *Mycoplasma* (see Chapter 20), and various aerobic and anaerobic bacteria. Bacterial infections have included pustules, abscesses, and fasciitis [579–583]. Infection rates are relatively low (0.1% to 4.5%) [579,580]; however, severe infections, including fasciitis, meningitis, and osteomyelitis, have occurred as severe complications. A review [581]

of causative organisms in fetal scalp monitor infections found that 61% of infections were polymicrobial, involving anaerobic bacteria, aerobic gram-positive cocci, and gram-negative bacilli.

A multitude of specific virulence factors may be important determinants of disease. Some phage types of *S. aureus* are responsible for local tissue damage and systemic disease; other staphylococci elaborate toxins that result in bullae and other cutaneous pathology. Groups A and B streptococci are responsible for cellulitis and impetigo in infants. *P. aeruginosa* may invade and proliferate in small blood vessels, causing local necrosis and eschar formation (i.e., ecthyma gangrenosum). Infections with *Clostridium* species cause disease in devitalized tissues such as the umbilical stump [584]. Similarly, organisms usually considered commensals, such as diphtheroids, might be responsible for infection of the cord and fetal membranes [585].

## MICROBIOLOGY

The skin of the infant is colonized initially by microorganisms present in the maternal birth canal. The skin of infants delivered by cesarean section is usually sterile at birth. After birth, microorganisms may be transferred to the skin during handling by the parents and nursery personnel. The prevalent organisms on the skin during the first few days of life include coagulase-negative staphylococci, diphtheroids, and gram-negative enteric bacilli (including *E. coli*) [586,587]. The umbilicus, genitalia, and adjacent skin areas (groin and abdomen) are colonized first; organisms then spread to the nose, throat, conjunctivae, and other body sites. Organisms present in the nursery environment colonize neonatal skin after a few days in the nursery. *S. aureus*, GBS, and various species of gram-negative bacilli may be present, but the microbiologic flora differs among nurseries and from time to time in the same nursery. Use of soaps and antiseptic solutions modifies the flora on the skin of the newborn. Hexachlorophene decreases colonization with staphylococci and diphtheroids, but gram-negative organisms are unaffected or may increase after use of this agent [588].

## EPIDEMIOLOGY

Infant boys are more susceptible to skin infections caused by *S. aureus* than girls. Thompson and coworkers [589] showed that boys were colonized more frequently in every body site cultured, including the nose, groin, rectum, and umbilicus. Their review of studies indicated that in England, the United States, and Australia, approximately 50% more boys had skin lesions than girls. Although the incidence of breast abscesses is equal in boys and girls during the first 2 weeks of life, such abscesses are more frequent thereafter in girls [590]. The reason for this pattern is unclear, but Rudoy and Nelson [590] hypothesized that physiologic breast enlargement may play a role. Hormone production in the female infant after the 2nd week might account for the increase in abscesses of the breast.

Infections caused by MRSA involving the skin of children and neonates have markedly increased. The *mecA* gene responsible for resistance to oxacillin and nafcillin is often closely linked to a gene responsible for skin invasion. Before 1997, epidemic MRSA infections occurred in neonatal units involving infections of the respiratory tract, nasopharynx, gastrointestinal tract, eye, blood, wounds, or umbilicus [591]; these infections were usually restricted to single nurseries and involved a single genetic variant of MRSA. Since 1990, MRSA infections acquired in the community have been reported with increased frequency [592], including in infants 2 weeks old. Of these infections, 91% have involved the skin and soft tissues. In contrast to typical nosocomial MRSA, community-acquired MRSA organisms have frequently remained susceptible to trimethoprim-sulfamethoxazole and clindamycin. At the University of New Mexico, continued surveillance of MRSA-colonized and MRSA-infected infants in NICUs showed that by 2003, more than half of all isolates were community acquired.

Seasonal variation in the frequency of neonatal skin infections has been reported by Evans and coworkers [593], who conducted a series of studies at Harlem Hospital in New York. The prevalence of *S. aureus*, *E. coli*, and streptococci in the nares and umbilicus of infants was lowest in the autumn and usually highest in the summer or spring. No seasonal variation was observed for *S. epidermidis* or *Enterobacter* species The investigators concluded that seasonal differences must be considered in investigations of bacterial colonization of the newborn skin, and that high humidity may favor gram-negative colonization.

The time of onset of skin lesions associated with sepsis may be early (during the 1st week of life) or late (several weeks or months after birth). Disease acquired in the nursery usually becomes apparent after 5 days of age. Many skin lesions do not appear until after the infant has left the nursery; the observed incidence of skin disease caused by bacteria should include surveillance of infants in the home during the 1st month of life. Physicians responsible for neonatal care must be alert to the unusual occurrence of skin lesions. The introduction of a new and virulent bacterium, an alteration in technique, or the use of contaminated materials must be considered as possible causes of an increased incidence of such infections.

## CLINICAL MANIFESTATIONS

Infants who have skin infections that remain localized that are not invasive or part of a systemic infection have few general signs of disease, such as fever, alteration in feeding habits, vomiting, or diarrhea. These signs may be present when significant tissue invasion occurs, as in abscesses or extensive cellulitis. Cutaneous manifestations that result from infectious diseases are listed in Table 10–5.

Among the common and least specific lesions are maculopapular rashes; these rashes may be caused by viruses (measles, rubella, or enteroviruses), fungi (*Candida* species), or bacteria (streptococci or staphylococci), or they may be unassociated with any infectious process. Erythema multiforme lesions have been observed in cases of sepsis related to *S. aureus* [594], streptococci [560], and *P. aeruginosa* [595]. Virtually any rash may be associated with bacterial infection. In an outbreak of sepsis caused by *Achromobacter* in premature infants [596], illness was

†*Including infections acquired in utero.*

marked by respiratory distress, including apnea and cyanosis, but was characterized by a rash consisting of indurated, erythematous lesions with sharply defined borders that began on the cheeks or chest and spread rapidly to adjacent areas.

Cellulitis, erysipelas, and impetigo are usually associated with streptococcal infection (group A or B) [597], although impetigo caused by *S. aureus* or *E. coli* has also been reported in infants. Vesicles, commonly associated with infections by herpesviruses, also are seen occasionally during early stages of skin lesions caused by *S. aureus*, *H. influenzae* [598], *L. monocytogenes* [599], and *P. aeruginosa*. GBS [600], *S. aureus*, *P. aeruginosa*, herpes simplex virus, and *T. pallidum* may also be responsible for bullous lesions. Pustules commonly occur in staphylococcal diseases, but also occur in infections caused by *L. monocytogenes* and, rarely, in skin infections with *H. influenzae* [601].

Ecthyma gangrenosum is a local manifestation of infection with *P. aeruginosa* [602,603]. Lesions begin as a vesicular eruption on a wide erythematous base. Vesicles rupture and form an indurated black eschar followed by larger, sharply demarcated, painless necrotic areas, resulting from a small vessel vasculitis with necrosis of the adjacent tissue. The organisms are present in purulent material underlying the necrotic membrane. These lesions are particularly more common adjacent to nose, lip, ear, mouth, and perineum, resulting in avascular necrosis and loss of tissue. *P. aeruginosa* may be grown in pure culture from blood and lesions. Among 48 infants described in one outbreak, lesions appeared within the first 2 weeks of life; most infants died within 3 days of onset [604]. Ecthyma is relatively specific for *Pseudomonas* infections, but similar or identical lesions have rarely been described in infections owing to *S. aureus*, *Aeromonas hydrophila*, *S. marcescens*, *Aspergillus* species, or *Mucor* species [605]

Many infants with *Candida* infections have cutaneous manifestations. Baley and Silverman [606] described 18 infants with systemic candidiasis; 8 had a burnlike truncal erythema, and 9 other infants had typical candidal diaper rashes or maculopapular rashes of the axillae or neck.

Abscesses of the skin and subcutaneous tissue are usually caused by *S. aureus* and, less frequently, by group A streptococci, GBS [607,608], or gram-negative enteric bacilli [609–617]. Community-acquired MRSA organisms are even more likely to produce skin infections with abscess formation. Organisms that colonize the skin over an area that has been disrupted by an abrasion or other wound may invade the subcutaneous tissue and produce an abscess. *Haemophilus* species [618–620], *Gardnerella vaginalis* [621], *Bacteroides* species [622], molluscum contagiosum [623], *Drosophila* myiasis [624], scabies [625], and *Candida* [626] are examples of diverse causes of cutaneous abscesses; virtually any bacterial, fungal, or parasitic agent that is normally or transiently on skin may become a pathogen. *E. coli*, *Klebsiella* species, *P. aeruginosa* [605,610,627], *N. gonorrhoeae* [628], and *Bacteroides fragilis* [629] have caused wound infections in infants whose scalps were lacerated by forceps, fetal electrodes, or instruments used for obtaining blood from the scalp in utero. An extensive outbreak of systemic disease caused by *S. marcescens* in an NICU in Puerto Rico included wound infections at the site of intravenous infusions.

A cephalhematoma may become infected during sepsis or from manipulation of the cephalhematoma, such as through diagnostic or therapeutic needle puncture [630] or by puncture from a fetal monitor. Infections may be caused by *Bacteroides* species [622], *E. coli* [609,610], and *P. aeruginosa* [631]. The infection may be associated with meningitis [631] or with osteomyelitis of the underlying skull [609,610].

*S. aureus* is the most frequent etiologic agent in breast abscess, but gram-negative enteric bacilli may be becoming more common [611,615,616]. Of 36 cases with mastitis seen in Dallas, Texas, during a 16-year period, 32 cases were caused by *S. aureus*, 1 was caused by *E. coli*, and 2 were caused by *Salmonella* species; both *E. coli* and *S. aureus* were isolated from one abscess [632]. At Children's Hospital in Boston from 1947-1983, 41 cases of mastitis in neonates were managed [633]. *S. aureus* was responsible for 29 of 34 cases with an identifiable bacterial pathogen. All cases occurred in term infants during weeks 1 to 5 of life. Bilaterality and extramammary foci were rare. One third of infants were febrile, and most had elevated white blood cell counts (>15,000 cells/mm$^3$). Other reports have identified GBS [608] and *P. mirabilis* [613] as causes of breast abscesses. Brook [616] found that 5 of 14 breast abscesses contained anaerobic bacteria (i.e., *Bacteroides* species and *Peptostreptococcus*), but *S. aureus*, GBS, or enteric bacteria predominated; anaerobic bacteria occurred alone in only 2 of 14 cases.

Paronychia may occur in neonates after injury to the cuticle. The lesion is usually caused by *S. aureus* or β-hemolytic streptococci [592]. The authors of a report on an outbreak of paronychia in a Kuala Lumpur nursery suggest but do not prove that the lesions were caused by an anaerobic *Veillonella* species [634].

Omphalitis is defined by the presence of erythema or serous or purulent discharge from the umbilical stump or periumbilical tissues. A review by Cushing [635] provided a useful discussion of the pathophysiology, microbiology, diagnosis, and management of omphalitis. The incidence of infection is more frequent in infants with low birth weight and infants with complications of delivery. A survey of infants born at the Royal Woman's Hospital in Brisbane, Australia [636], identified an incidence of approximately 2% among term infants. The mean age of infants at presentation of omphalitis was 3.2 days. Perhaps because hexachlorophene bathing was used, gram-negative bacilli were more frequently associated with infection than gram-positive cocci. Microbiologic results are difficult to interpret, however, because swabs of the site of infection do not exclude surface contaminants, unless cultures are taken with extreme care and precision.

A series from the United States [637] found that periumbilical fasciitis was more frequent in boys, but did not find that umbilical catheterization, low birth weight, or septic delivery was associated with a high risk; overall, the incidence of omphalitis was equal in boys and girls. In this series, omphalitis manifested as discharge, cellulitis, or fasciitis; gram-positive organisms were found in 94% of cultures, and gram-negative bacteria were found in 64%. *S. aureus* was the most frequent isolate, with *E. coli* and *Klebsiella* species the next most common. Group A

streptococci have been responsible for nursery outbreaks that may include an indolent form of omphalitis characterized by erythema and oozing of the umbilical stump for days to weeks, accompanied by pustular lesions of the abdominal wall in some cases [638]. Neonatal tetanus usually occurs as a result of contamination of the umbilical wound by *Clostridium tetani* at delivery.

Acute necrotizing fasciitis is a bacterial infection of subcutaneous tissue and fascial sheath [614,639,640]. Infection can arise in an operative wound or in a focal infection, such as a breast abscess, or there may be no apparent predisposing cause. Necrotizing fasciitis has been reported after circumcision [577] and as a complication of insertion of a fetal monitor [641]. The trunk and extremities are the areas most commonly involved; inflammation spreads rapidly along fascial planes, producing thrombosis and extensive necrosis, with infarcts developing in overlying skin. Vesicles and bullae appear, and the skin may become blue-gray or black. Myositis and bacteremia may accompany fasciitis. Staphylococci, GBS [642], *E. coli*, *P. aeruginosa*, anaerobic bacteria [643], and mixtures of gram-positive and gram-negative bacteria have been associated with this disease. The bacteria are present in skin lesions, deep fascia, and, in some cases, blood. The mortality is high despite the use of fasciotomy, wide débridement, and antibiotics.

Perirectal abscesses may occur in newborns. In contrast to older children, most newborns with perirectal abscess do not have underlying immunodeficiency, although infants with acquired or congenital immunodeficiency often present with this condition. The most common causes of perirectal abscess are *S. aureus*, *E. coli*, or other enteric bacilli [644,645]; however, anaerobic bacteria can also be involved. *S. aureus* and enteric bacilli may be more common in infants and newborns [645]. Recent rectal surgery for conditions such as Hirschsprung disease or imperforate anus (myotomy or rectal dilation) may be predisposing causes in infants; as in older children, neutropenia may be associated with an increased risk for perirectal abscess.

Otitis externa is uncommon in newborns. Victorin [646] described an outbreak of neonatal infections in which *P. aeruginosa* was cultured from seven infants with suppuration of the auditory canal. The author suggested that this outbreak was caused by contaminated bath water used in the nursery.

## DIAGNOSIS

The appearance of a skin lesion alone may be sufficiently typical to suspect certain etiologic agents (e.g., ecthyma gangrenosum), but more often, the appearance is nonspecific. A microbiologic diagnosis should be sought to provide specific therapy. The lesion and the surrounding tissue should be cleaned with 70% ethanol to prevent contamination from organisms that colonize the surface. If crusts are present, they should be lifted with a sterile swab to provide drainage, and cultures should be obtained from the base of the lesion.

Vesicles and pustules can be aspirated with a needle (20-gauge to 25-gauge) attached to a syringe, or they can be opened and exudate can be collected on a sterile swab. Generally, swabs are not preferred for specimen collection because swab materials bind or inactivate bacterial organisms. Aspiration of abscesses is important; more than one aspiration may be required because the suppurative focus may not be easily distinguished from the surrounding inflammatory tissue. Aspiration of the leading edge or point of maximal inflammation of an area of cellulitis may be valuable and should be performed if no other suppurative or purulent sites are available for culture. A small needle (25-gauge or 26-gauge) should be attached to a tuberculin or other small-volume syringe filled with 0.25 to 0.50 mL of sterile nonbacteriostatic saline; the needle should be inserted into the area of soft tissue to be sampled, with continuous, gentle aspiration applied to the syringe. If no fluid is returned to the syringe, a small amount of fluid should be injected and immediately aspirated back into the syringe. Collected material may be sent to the laboratory in the syringe for Gram stain and culture, or, alternatively, the contents may be washed into a tube of bacteriologic broth medium for transport and subsequent culture.

If swabs are used, care must be taken that the material does not dry before it is plated on bacteriologic media. Swabs preferentially should be directly inoculated or rinsed in bacteriologic media and immediately transported to the microbiology laboratory. Alternatively, they may be refrigerated or placed in appropriate transport media if more than a few hours will elapse before inoculation of media in the laboratory. Whenever sufficient material is available (on swabs or in liquid), several slides should be prepared for Gram staining.

It is often difficult to distinguish petechiae from vascular dilation. Pressure with a glass slide on the border of the lesion is a simple and reliable method for detecting extravasation of red blood cells. If the lesion disappears on pressure, it is probably caused by dilation of small vessels, whereas persistence of the lesion after application of pressure indicates extravasation of red blood cells. Bacteria may be present in petechial lesions that occur in infants with bacterial sepsis. Blood obtained by aspiration or gentle scraping with a scalpel at the center of the petechiae may reveal the causative organism on Gram stain or culture.

## DIFFERENTIAL DIAGNOSIS

Sclerema neonatorum, milia, and erythema toxicum are noninfectious lesions that are often confused with infections of the skin [647]. Bullous and purpuric lesions may be caused by noninfectious disorders, including mast cell diseases (e.g., urticaria pigmentosa), histiocytosis X, acrodermatitis enteropathica, dermatitis herpetiformis, epidermolysis bullosa, congenital porphyria [562], and pemphigus vulgaris [648]. A syndrome of generalized erythroderma, failure to thrive, and diarrhea has been associated with various forms of immunodeficiency [649].

Sclerema neonatorum is a diffuse, spreading, waxy hardness of the skin and subcutaneous tissue that occurs during the first weeks of life [628,650]. The subcutaneous tissue seems to be bound to underlying muscle and bone. This condition is usually seen on the thighs, buttocks, and trunk. Although associated with sepsis in some infants,

sclerema also affects infants with dehydration, acidosis, and shock. Most evidence supports the hypothesis that sclerema is a manifestation of shock and insufficiency of the peripheral circulation. When it occurs in infants with generalized infection, sclerema is associated with a poor prognosis. In a review of cases of sepsis at The New York Hospital, sclerema was detected in 6 of 71 infants, 5 of whom died [651].

Milia are yellow or pearly white papules that are 1 mm in diameter and usually found scattered over the cheeks, forehead, and nose [647,652]. The lesion is a small cyst formed from retention of sebum in sebaceous glands. Because the cyst is capped by a shiny surface of epidermis, it may be confused with a small pustule. Milia are common; Gordon [652] estimated that 40% of healthy newborns have milia. The lesions are common in the first few weeks of life. These cysts may be distinguished from staphylococcal pustules by aspiration and Gram stain of the material.

Erythema toxicum consists of several types of lesions, including 1- to 3-mm, yellow-white papules or pustules on an erythematous base, erythematous macules, or diffuse erythema. These lesions are usually present on the trunk, but may involve the head and neck and extremities as well. Most lesions appear within the first hours of life and are uncommon after 2 days of age. Erythema toxicum is uncommon in low birth weight or premature infants [653]. Affected infants have no signs of systemic illness or local irritation. A smear of the contents of pustules reveals the presence of eosinophils and an absence of bacteria. Other noninfectious pustular lesions of newborns include neonatal pustular melanosis, which is marked by a mixed infiltrate that has a predominance of neutrophils [654], and infantile acropustulosis, which is characterized by an eosinophilic infiltration of the skin [655,656].

Bullae may occur on the skin of the wrist or forearm and usually are caused by trauma [657]. Sucking of the extremity by the infant is believed to cause the bullae, which contain sterile serous fluid. Purpura may be caused by noninfectious conditions, including trauma; erythroblastosis fetalis; or, less frequently, coagulation disorders, maternal drug ingestion, congenital leukemia, and congenital Letterer-Siwe disease.

Diaper rash is primarily a contact dermatitis associated with soilage of the skin by urine and stool [658–660]. The rash may occur as a mild erythema or scaling, a sharply demarcated and confluent erythema, or discrete shallow ulcerations. A beefy red, confluent rash with raised margins, satellite (e.g., folliculitis) oval lesions, or discrete vesicular-pustular lesions indicates secondary invasion by *C. albicans* or *S. aureus*. Systemic infectious illnesses that manifest as disseminated rashes (e.g., herpes, varicella, syphilis) may be characterized by early typical lesions in the diaper area.

## TREATMENT

The treatment of localized skin lesions consists of the use of local antiseptic materials, systemic antimicrobial agents, and appropriate incision and drainage or débridement. Hexachlorophene (3% detergent emulsion) and chlorhexidine (4% solution) are valuable in cleaning small, abraded areas and discrete pustular lesions. Because of concern over its neurotoxicity and cutaneous absorption, hexachlorophene should not be used on large open areas of skin (see Chapter 14).

Systemic antibiotics should be considered for therapy whenever there is significant soft tissue infection with abscess or cellulitis. The specific antibiotic choice should be made on the basis of the microbiology of the lesion; streptococci may be treated effectively with penicillin G, ampicillin, or extended-spectrum cephalosporins (i.e., cefotaxime or ceftriaxone), whereas staphylococci generally must be treated with penicillinase-resistant penicillins or vancomycin. Infections owing to gram-negative enteric bacilli may be treated with aminoglycosides or extended-spectrum cephalosporins based on the results of susceptibility testing. Infections owing to *Pseudomonas* organisms can be effectively treated with aminoglycosides or ceftazidime.

Local heat and moist dressings over areas of abscess formation may facilitate localization or spontaneous drainage. Indications for incision and drainage of abscesses in infants are the same as for the indications in older children and adults.

## PREVENTION

Prevention of local skin infections is best provided by appropriate routine hygiene, maintenance of the integrity of skin (i.e., avoidance of drying, trauma, or chemical contact), frequent diaper changes, and hygienic care of the umbilicus or other wounds or noninfectious skin inflammation. The following measures of skin care are recommended by the Committee of the Fetus and Newborn of the American Academy of Pediatrics [660] to prevent infection:

1. The first bath should be postponed until the infant is thermally stable.
2. Nonmedicated soap and water should be used; sterile sponges (not gauze) soaked in warm water may be used.
3. The buttocks and perianal should be cleaned with fresh water and cotton or with mild soap and water at diaper changes.
4. Ideally, agents used on the newborn skin should be dispensed in single-use containers.
5. No single method of cord care has proved to be superior, and none is endorsed [660].

Cord care may include application of alcohol, triple dye (i.e., brilliant green, proflavine hemisulfate, and crystal violet), or antimicrobial agents such as bacitracin. Alcohol hastens drying of the cord, but is probably not effective in preventing cord colonization and omphalitis. A randomized study of triple dye, povidone-iodine, silver sulfadiazine, and bacitracin ointment showed comparability in antimicrobial control [661].

During nursery outbreaks, the Centers for Disease Control and Prevention recommends the judicious use of hexachlorophene bathing [662]. Daily hexachlorophene bathing of the diaper area [663] and umbilical cord care with 4% chlorhexidine solution [664] have shown efficacy for prevention of staphylococcal disease (see Chapter 14).

## CONJUNCTIVITIS AND OTHER EYE INFECTIONS

Conjunctivitis in the newborn usually results from one of four causes: infection with *N. gonorrhoeae*, infection with *S. aureus*, inclusion conjunctivitis caused by *Chlamydia trachomatis*, or chemical conjunctivitis caused by silver nitrate solution [665,666]. Less commonly, other microorganisms have been implicated as a cause of conjunctivitis, including group A streptococci, GBS, *S. pneumoniae*, *H. influenzae* (nontypable [591] and group b [667]), *P. aeruginosa*, *Moraxella* (*Neisseria*) *catarrhalis* [668], *Neisseria meningitidis* [669], *Corynebacterium diphtheriae* [670], *Pasteurella multocida* [671], *Clostridium* species [672], herpes simplex virus, echoviruses, *M. hominis*, and *Candida* species. In addition to meningococcal infections, other *Neisseria* species can be confused with gonococcal infections; *Neisseria cinerea* has been reported to cause conjunctivitis that was indistinguishable from gonococcal infection [673].

An epidemic of erythromycin-resistant *S. aureus* conjunctivitis affected 25 of 215 newborns during a 10-month period; control of the epidemic was achieved by identification of staff carriers and substitution of silver nitrate prophylaxis for erythromycin [674]. The major causes of conjunctivitis in neonates are discussed in Chapters 14 and 15. Cultures of the conjunctivae of neonates with purulent conjunctivitis and from the comparable eyes of a similar number of infants chosen as controls revealed significant differences, suggesting causality for viridans streptococci, *S. aureus*, *E. coli*, and *Haemophilus* species [675,676] MRSA infections may have an increased propensity to infect the eye. Conjunctivitis owing to MRSA was reported as the first case in an epidemic that eventually involved 14 neonates in an NICU including multiple invasive infections and two deaths [677]. MRSA has also caused dacrocystitis [678] and keratitis [679] in neonates.

Compared with chemical (e.g., silver nitrate) conjunctivitis, other noninfectious causes for conjunctivitis occur only rarely. Eosinophilic pustular folliculitis has been described since 1970 [680] although this disease usually occurs after 3 months of age, some infants younger than 4 to 6 weeks have been described. These infants present with recurrent crops of pruritic papules primarily affecting the scalp and brow. Biopsy specimens reveal folliculitis with a predominant eosinophilic infiltrate; most infants also have a leukocytosis and eosinophilia. Other acute or chronic cutaneous conditions may also manifest as conjunctival or periorbital inflammation, such as seborrhea, atopic dermatitis, acropustulosis of infancy, and erythema toxicum (see "Infections of the Skin and Subcutaneous Tissue").

In a review by Hammerschlag [681], the incidence of the two major pathogens ranged from 17% to 32% for *C. trachomatis* and 0% to 14.2% for *N. gonorrhoeae* in four U.S. studies. In other developed countries such as England [682], investigators found 8 cases of gonococcal infection and 44 cases of chlamydial infection among 86 newborns with ophthalmia neonatorum; in Denmark [683], investigators found that 72% of infants with conjunctivitis at 4 to 6 days after birth had positive cultures, but 70% were caused by staphylococci (*S. aureus* and *S. epidermidis*), and chlamydiae were isolated from only 2 of 300 newborns.

The incidence and microbiology of neonatal conjunctivitis depend on the incidence of transmissible infections in the maternal genital tract or the nursery and the use and efficacy of chemoprophylaxis. In Nairobi, Kenya, in a hospital where ocular prophylaxis had been discontinued, the incidence of gonococcal and chlamydial ophthalmitis was 3.6 and 8.1 cases per 100 live births [684]; in Harare, Zimbabwe, in a hospital where prophylaxis also was not used, the most common cause of conjunctivitis was *S. aureus* [685]. The introduction of tetracycline ointment for prophylaxis at Bellevue Hospital in New York City led to an overall increase in conjunctivitis associated with an increase in the incidence of gonococcal infection [686] because of the emergence of tetracycline resistance among gonococci.

Infections related to *P. aeruginosa* warrant special attention. Although uncommon, pseudomonal conjunctivitis may be a devastating disease if not recognized and treated appropriately [686]. The infection is usually acquired in the nursery, and the first signs of conjunctivitis appear between the 5th and 18th days of life. At first, the clinical manifestations are localized to the eye and include edema and erythema of the lid and purulent discharge. In some children, the conjunctivitis progresses rapidly, with denuding of the corneal epithelium and infiltration with neutrophils. With extension of the corneal infiltration, perforation of the cornea may occur. The anterior chamber may fill with fibrinous exudate, and the iris can adhere to the cornea. Subsequent invasion of the cornea by small blood vessels (pannus) is characteristic of pseudomonal conjunctivitis. The late ophthalmic complications may be followed by bacteremia and septic foci in other organs [687].

Pseudomonal eye infections in neonates can occur in epidemic form, with subsequent high rates of mortality and ophthalmic morbidity. Burns and Rhodes [687] reported a series of eye infections caused by *P. aeruginosa* in premature infants with purulent conjunctivitis rapidly progressing to septicemia, shock, and death in four infants. Five other children with conjunctivitis alone survived, but one child required enucleation. Drewett and coworkers [688] described a nursery outbreak of pseudomonal conjunctivitis believed to be caused by contaminated resuscitation equipment; of 14 infected infants, 1 became blind, and 1 had severe corneal opacities. Rapidity of the course of this infection is indicated in a case report of a 10-day-old infant who developed a corneal ulcer with perforation within 2 days after first observation of a purulent discharge [689]. An outbreak of four cases of *Pseudomonas* conjunctivitis in premature infants occurred within 2 weeks at the American University of Beirut Medical Center [690]; no cause for the outbreak was found.

A review by Lohrer and Belohradsky [691] of bacterial endophthalmitis in neonates emphasizes the importance of *P. aeruginosa* in invasive bacterial eye infections ranging from keratitis to panophthalmitis. The literature review included 16 cases of invasive eye infections in neonates; 13 were caused by *P. aeruginosa*, and the others were cases of endophthalmitis caused by GBS and *S. pneumoniae*. Other opportunistic gram-negative pathogens associated with outbreaks of infections in nurseries may also include conjunctivitis as a part of the infection syndrome. In a report by Christensen and coworkers [692], multiply antibiotic-resistant *S. marcescens* was responsible for 15 cases of pneumonia, sepsis, and meningitis and for

20 cases of conjunctivitis, cystitis, and wound infection over a 9-month period in an NICU.

Dacryocystitis may complicate a congenital lacrimal sac distention (i.e., dacryocystocele) which may appear as early as the during the first week of life with edema and erythema of the lower lid. Purulent material emerged from the puncta after moderate pressure over the lacrimal sac; *S. marcescens* was grown from the material.

The physician responsible for management of a child with purulent conjunctivitis must consider the major causes of the disease and must be alert to rare pathogens. In hospitals that practice Credé method (i.e., silver nitrate application), purulent conjunctivitis during the first 48 hours of life is almost always caused by chemical toxicity [694]. After the first 2 days, the pus of an exudative conjunctivitis must be carefully examined by Gram stain for the presence of gram-negative intracellular diplococci, gram-positive cocci in clusters, and gram-negative bacilli. Appropriate cultures should be used for isolation of the organisms concerned. If the smears are inconclusive and no pathogens are isolated on appropriate media, and if conjunctivitis persists, a diagnosis of inclusion or chlamydial infection is likely [693,694].

The treatment of staphylococcal and gonococcal conjunctivitis is discussed in Chapters 14 and 15. Chlamydial conjunctivitis is reviewed in Chapter 19.

If infection with *Pseudomonas* species is suspected, treatment should be started at once with an effective parenteral antibiotic, such as an aminoglycoside (e.g., tobramycin, amikacin, or gentamicin) with or without an antipseudomonal penicillin or ceftazidime (see Chapter 35) and with a locally applied ophthalmic ointment. The use of subconjunctival gentamicin or other antipseudomonal aminoglycoside is of uncertain value; however, if the cornea seems to be extensively involved, there is a risk of rapid development of endophthalmitis, and the subconjunctival injection of antibiotics should be considered in consultation with an ophthalmologist. If the diagnosis is confirmed, this regimen is continued until the local signs of *Pseudomonas* infection resolve.

Recommendations for ocular chemoprophylaxis are discussed in Chapters 15 and 19. Additional information is available in the 2009 edition of the *Report of the Committee on Infectious Diseases* published by the American Academy of Pediatrics [695].

CHAPTER 11

# MICROORGANISMS RESPONSIBLE FOR NEONATAL DIARRHEA

**Miguel L. O'Ryan ◎ James P. Nataro ◎ Thomas G. Cleary**

## CHAPTER OUTLINE

Diarrheal disease continues to be a significant cause of morbidity and mortality worldwide in the 21st century. During the period 1986-2000, an estimated 1.4 billion children younger than 5 years old had an episode of acute diarrhea every year in developing countries; among these, 123.6 million required outpatient medical care, and 9 million required hospitalization. Approximately 2 million diarrhea-associated deaths occurred in this age group annually, primarily in the most impoverished areas of the world [1]. These estimates are decreased from the more than 3 million annual deaths from diarrhea reported in the prior 10 years [2], indicating progress in prevention and treatment of acute diarrhea. In the United States, approximately 400 childhood deaths per year were reported during the late 1980s [3,4], although the actual number may be higher [4].

Nearly 4 million infants die every year in the first 4 weeks of life [5]. Infections account for 36% of these deaths, of which diarrhea causes 3%, accounting for approximately 110,000 deaths (range 80,000 to 410,000) per year [5,6]. These deaths are concentrated in countries with neonatal mortality rates of 30 or more per 1000 live births, mainly in Africa and Southeast Asia. In Haiti, diarrhea was not detected in a small series of 34 cases of neonatal deaths [7]. In India, diarrhea caused 10% of severe illness requiring hospitalization among newborns 7 to 27 days of age [8]. The relative sparing of most newborns probably results from low exposure to enteropathogens and protection associated with breast-feeding [9–13]. After the first few months of life, increasing interaction with other individuals and the environment, including the introduction of artificial feeding, increases the risk of exposure to enteropathogens. For infants with very low birth weight (<1500 g), the death rate from diarrhea is 100-fold greater than for infants with higher birth weight [14].

This chapter discusses the pathogenesis, diagnosis, treatment, and prevention of gastroenteritis based on the available knowledge about pathogens that can cause neonatal diarrhea. Pathogens that rarely or never cause acute diarrhea in neonates are mentioned and discussed briefly. After an overview of host defense mechanisms and protective factors in human milk, the remainder of the chapter is devoted to specific pathogens that cause inflammatory or noninflammatory diarrhea.

## ENTERIC HOST DEFENSE MECHANISMS

Significant research, mostly in animal models, has been performed to understand the relationship between the gut and commensal and pathogenic microorganisms. The mechanisms, cells, and molecules involved in microorganism-intestinal interactions are numerous, increasingly complex, and only partially understood. A complete review of this topic is beyond the scope of this chapter; comprehensive reviews on intestinal immunity have been published [15,16], including specific reviews on dendritic cells [17], intestinal IgA [18], intestinal epithelial cells [19], microbial colonization [20], toll-like receptors [21], mast cells [22], and Paneth cells [23]. It is generally accepted that although most of the constituents required for an intestinal immune response against microorganisms are present in the neonatal gut, they are "immature," principally because neonates have not had the opportunity to develop local or systemic immune responses, and in the first few days of life, they have yet to acquire the highly important enteric microflora that protects the normal adult gastrointestinal (GI) tract [9,24–29]. During the early neonatal period, there is a "relative" deficiency in antigen-presenting cell functions and altered cell-mediated immune responses [30]. Little is known about the barrier capabilities of the neonate's

DOI: 10.1016/B978-1-4160-6400-8.00011-0

gastric acidity [30,31], intestinal mucus [30,32], or motility [33,34], each of which provides protection against GI tract infections in older infants, children, and adults.

The gastric acid barrier seems to be least effective during the first months of life. The average gastric pH level of the newborn is high (pH 4 to 7, mean 6) [35,36]. Although the pH falls to low levels by the end of the first day of life (pH 2 to 3) [35], it subsequently rises again; by 7 to 10 days of life, the hydrochloric acid output of the neonatal stomach is far less than that of older infants and children [36,37]. The buffering action of frequent milk feedings and the short gastric emptying time [38–41] introduce additional factors in the neonate that would be expected to permit viable ingested organisms to reach the small intestine.

Immediately after birth, infants begin to acquire commensal microorganisms from their surroundings. Factors that regulate this acquisition and the degree of variation within and between individuals are only partially understood. Commensal bacteria seem to be acquired as a result of random environmental encounters most likely influenced by feeding patterns (human versus formula milk). The consequences of alterations in the acquisition or composition, or both, of commensal bacterial communities on mammalian development, normal physiology, and susceptibility to disease are an active area of investigation [19,29].

The intestinal epithelium serves as a nutrient absorptive machine, barrier to pathogen entry, regulator of inflammation, and critical element in maintaining immune homeostasis of the gut [19,42]. The thick mucin-rich glycocalix surrounded by mucus forms a physical barrier embedded with antimicrobial peptides and enzymes [30]. The different composition of adult and neonatal glycocalix may influence susceptibility to colonization and infection [30]. Intestinal epithelial cells have receptors for bacterial products and produce chemokines (e.g., interleukin-8, monocyte chemotactic protein type 1, granulocyte-macrophage colony-stimulating factor) and proinflammatory cytokines (e.g., interleukin-6, tumor necrosis factor-α, interleukin-1) in response to invasion by enteropathogens [43]. The gut epithelium orchestrates the immune response. Paneth cells in crypts express toll-like receptors activated by microorganisms leading to release of potent antimicrobial agents including lysozyme and cryptidins [44].

Neonatal B-lymphocyte and T-lymphocyte functions are impaired, resulting in preferential IgM production in response to antigenic stimulation. IgG is actively transferred from mother to infant across the placenta at about 32 weeks of gestation and peaks by about 37 weeks. Premature neonates, especially infants born before 28 weeks' gestation, are deficient in these maternally derived serum antibodies [29,30,44,45].

## PROTECTIVE FACTORS IN HUMAN MILK

The importance of breast-feeding to infants for the prevention of diarrheal disease has long been emphasized [9,46–59]. Published studies reporting the association between breast-feeding and diarrhea are extensive and suggest that infants who are breast-fed have fewer episodes of diarrhea than infants who are formula-fed. This protection is greatest during an infant's first 3 months of life and declines with increasing age. During the period of weaning, partial breast-feeding confers protection that is intermediate between the protection gained by infants who are exclusively breast-fed and that by infants who are exclusively formula-fed.

Mata and Urrutia [9] provided a striking demonstration of the protection afforded by breast-feeding of newborns in their studies of a population of infants born in a rural Guatemalan village. Despite extremely poor sanitation and the demonstration of fecal organisms in the colostrum and milk of almost one third of mothers [60], diarrheal disease did not occur in any of the newborns. The incidence of diarrhea increased significantly only after these infants reached 4 to 6 months old, at which time solids and other fluids were used to supplement the human milk feedings. At that time, *Escherichia coli* and gram-negative anaerobes (e.g., *Bacteroides* species) were found to colonize the intestinal tract [9]. In contrast, urban infants of a similar ethnic background who were partly or totally artificially fed frequently acquired diarrheal disease caused by enteropathogenic *E. coli* (EPEC). A more recent study among infants 0 to 3 months old from Bangladesh showed that breast-feeding provided significant protection against diarrheal disease with an adjusted odds ratio of 0.69 (95% confidence interval 0.49-0.98) and respiratory disease with an adjusted odds ratio of 0.69 (95% confidence interval 0.54-0.88) [61]. Protection afforded by breast-feeding against diarrhea during the first months of life has also been observed in more industrialized societies such as the United Kingdom [62].

Multiple mechanisms by which breast-feeding protects against diarrhea have been postulated. Breast-feeding confers protection by active components in milk and by decreased exposure to organisms present on or in contaminated bottles, food, or water. Many protective components have been identified in human milk and generally are classified as belonging to the major categories of cells, antibodies, anti-inflammatory factors, and glycoconjugates and other nonantibody factors [12,63–65]. Examples of milk antibodies are summarized in Table 11–1.

For any given pathogen, multiple milk factors may help protect the infant. Human milk typically targets a major

**TABLE 11–1** Association between Antibodies in Human Milk and Protection against Enteropathogens

| Organism | Antibody |
|---|---|
| *Vibrio cholerae* | Lipopolysaccharide, enterotoxin |
| *Campylobacter jejuni* | Surface proteins |
| Enteropathogenic *Escherichia coli* | Adherence proteins |
| Enterotoxigenic *E. coli* | Enterotoxin, adherence proteins |
| Shigatoxin-producing *E. coli* | Adherence proteins |
| *Shigella* | Lipopolysaccharide, virulence plasmid–associated antigens |
| *Giardia lamblia* | Surface proteins |

pathogenic mechanism using multiple, redundant strategies. Redundancy of milk protective factors and targeting of complex virulence machinery have created a formidable barrier to enteropathogens. Despite the fact that pathogens can rapidly divide and mutate, milk continues to protect infants. Human milk has secretory antibodies to *Shigella* virulence antigens and lipopolysaccharides [66,67], neutral glycolipid Gb3 to bind Shiga toxin [68,69], and lactoferrin to disrupt and degrade the surface-expressed virulence antigens. Lactoferrin chelates iron, making it unavailable for bacterial metabolism; stimulates phagocytosis; and inhibits several viruses, such as human immunodeficiency virus (HIV), cytomegalovirus, and herpes simplex virus [30,70–72]. In a similar way, milk contains antibodies directed toward the surface-expressed virulence antigens of EPEC [73], oligosaccharides that block EPEC cell attachment [74], and lactoferrin interference with EPEC surface factors [75]. Human milk can initiate and maintain the growth of *Bifidobacterium* species and low pH in the feces of newborn infants, creating an environment antagonistic to the growth of *E. coli* [9,27,28,76]. Lysozyme in human milk breaks β1,4 bonds between *N*-acetylmuramic acid and *N*-acetylglucosamine, a critical linkage in the peptidoglycans of bacterial cell walls [30].

The protective effect of human milk antibodies against enteropathogen-specific disease has been described for *Vibrio cholerae* [77], *Campylobacter jejuni* [78], EPEC [74], enterotoxigenic *E. coli* (ETEC) [79,80], *Shigella* species [81,82], and *Giardia lamblia* [83,84]. Protective effects for bovine milk concentrate against ETEC [85], rotavirus [86], and *Shigella* species have also been described [87].

In 1933, the nonlactose carbohydrate fraction of human milk was found to consist mainly of oligosaccharides [88]. In 1960, Montreuil and Mullet [89] determined that oligosaccharides constituted 2.4% of colostrum and 1.3% of mature milk. Human milk contains a larger quantity of oligosaccharides than milk from other mammals, and its composition is singularly complex [90]. The metabolic fate of oligosaccharides is of interest. Only water, lactose, and lipids are present in greater amounts than oligosaccharides. Despite the fact that substantial energy must be expended by the mother to synthesize the many hundreds of different milk oligosaccharides, the infant does not use them as food. Most of the oligosaccharides pass through the gut undigested [91,92]. It is thought that they are present primarily to serve as receptor analogues that misdirect enteropathogen attachment factors away from gut epithelial carbohydrate receptors. Likewise, enteropathogens use the oligosaccharide portion of glycolipids and glycoproteins as targets for attachment of whole bacteria and toxins. Evidence is emerging that these glycoconjugates may have an important role in protection of the breast-fed infant from disease [64].

Human milk protects suckling mice from the heat-stable enterotoxin (ST) of *E. coli*; on the basis of its chemical stability and physical properties, the protective factor has been deduced to be a neutral fucosyloligosaccharide [93,94]. Experiments have shown that EPEC attachment to HEp-2 laryngeal epithelial cells and HIV-1 binding to dendritic cell coreceptor DC-SIGN can be inhibited by purified oligosaccharide fractions from human milk [74].,[93a] Oligosaccharides also may be relevant to protection from Norwalk virus and other caliciviruses because these viruses attach to human ABO, Lewis, and secretor blood group antigens [94,95]. Human milk contains large amounts of these carbohydrates. The ganglioside fraction in human milk has been shown to inhibit the action of heat-labile toxin (LT) and cholera toxin on ileal loops more effectively than secretory IgA [96,97]. Lactadherin in human milk has been shown to bind rotavirus and to inhibit viral replication in vitro and in vivo [98]. A study of infants in Mexico showed that lactadherin in human milk protected infants from symptoms of rotavirus infection [87]. Free fatty acids and monoglyceride products of lingual and gastric lipase activity in human milk triglycerides may have antiviral and antiparasitic activity [30]. Human milk oligosaccharides also inhibit leukocyte endothelial adhesion and help explain the low rate of inflammatory disorders in breast-fed infants [98a].

## BACTERIAL PATHOGENS

### ESCHERICHIA COLI

*E. coli* promptly colonize the lower intestinal tracts of healthy infants in the first few days of life [99–102] and constitute the predominant aerobic coliform fecal flora throughout life in humans and in many animals. The concept that this species might cause enteric disease was first suggested in the late 19th and early 20th centuries, when several veterinary workers described the association of diarrhea (i.e., scours) in newborn calves with certain strains of *E. coli* [103–108].

In 1905, Moro [109] observed that *Bacterium* (now *Escherichia*) *coli* was found more often in the small intestines of children with diarrhea than in children without diarrhea. Adam [110,111] confirmed these findings and noted the similarity with Asiatic cholera and calf scours. He extended these observations further by suggesting that *E. coli* strains from patients with diarrhea could be distinguished from normal coliform flora by certain sugar fermentation patterns. Although Adam called these disease-producing organisms "dyspepsicoli" and introduced the important concept that *E. coli* could cause enteric disease, biochemical reactions have not proved to be a reliable means of distinguishing nonpathogenic from pathogenic *E. coli* strains. There are now at least six recognized enteric pathotypes of *E. coli* [112]. The pathotypes can be distinguished clinically, epidemiologically, and pathogenetically (Table 11–2) [112–120].

ETEC organisms are defined by their ability to secrete LT or ST enterotoxin, or both. LT is closely related to cholera toxin and similarly acts by means of intestinal adenylate cyclase [121,122], prostaglandin synthesis [123,124], and possibly platelet-activating factor [125,126]. ST (particularly the variant STa) causes secretion by specifically activating intestinal mucosal guanylate cyclase [127–129]. STb toxin stimulates noncyclic, nucleotide-mediated bicarbonate secretion and seems to be important only in animals [130–132]. Enteroinvasive *E. coli* (EIEC) has the capacity to invade the intestinal mucosa, causing inflammatory enteritis similar to shigellosis [133,134]. EPEC elicits diarrhea by a signal transduction mechanism [112–118,135,136], which

is accompanied by a characteristic attaching-and-effacing histopathologic lesion in the small intestine [137]. Enterohemorrhagic *E. coli* (EHEC) also induces an attaching-and-effacing lesion, but in the colon [112]. EHEC secretes Shiga toxin, which gives rise to the dangerous sequela of hemolytic-uremic syndrome (HUS). Diffusely adherent *E. coli* [138] executes a signal transduction effect, which is accompanied by the induction of long cellular processes [139]. Enteroaggregative *E. coli* (EAEC) adheres to the intestinal mucosa and elaborates enterotoxins and cytotoxins [112,119,140].

A major problem in the recognition of ETEC, EIEC, EPEC, and EHEC strains of *E. coli* is that they are indistinguishable from normal coliform flora of the intestinal tract by the usual bacteriologic methods. Serotyping is valuable in recognizing EPEC serotypes [141] and EIEC because these organisms tend to fall into a few specific serogroups (see Table 11–2) [141,142]. EIEC invasiveness is confirmed by inoculating fresh isolates into guinea pig conjunctivae, as described by Sereny [143]. The ability of organisms to produce enterotoxins (LT or ST) is encoded by a transmissible plasmid that can be lost by one strain of *E. coli* or transferred to a previously unrecognized strain [144–146]. Although the enterotoxin plasmids seem to prefer certain serogroups (different from EPEC or invasive serogroups) [147], ETEC is not expected to be strictly limited to a particular set of serogroups. Instead, these strains can be recognized only by identifying the enterotoxins or the genes encoding them. The toxin can be assayed in ligated animal loops [150], in tissue culture [151,152], or by enzyme-linked immunosorbent assay (ELISA) [153] for LT or in a suckling mouse model for ST [154,155]. Specific DNA probes and, more importantly, polymerase chain reaction (PCR) assays are available to detect LT and ST genes [112–114]. The various *E. coli* pathotypes are generally attended by a broad array of primary and accessory virulence factors, as discussed subsequently [156–158].

## Enterotoxigenic *Escherichia coli*

Although early work on the recognition of *E. coli* as a potential enteric pathogen focused on biochemical or serologic distinctions, there followed a shift in emphasis to the enterotoxins produced by previously recognized and entirely "new" strains of *E. coli*. Beginning in the mid-1950s with work by De and colleagues [159,160] in

Calcutta, *E. coli* strains from patients with diarrhea were found to cause a fluid secretory response in ligated rabbit ileal loops analogous to that seen with *V. cholerae*. Work by Taylor and associates [161,162] showed that the viable *E. coli* strains were not required to produce this secretory response and that enterotoxin production correlated poorly with classically recognized EPEC serotypes. In São Paulo, Trabulsi [163] made similar observations with *E. coli* isolated from children with diarrhea, and several veterinary workers showed that ETEC was associated with diarrhea in piglets and calves [164–167]. A similar pattern was described in 1971, when *E. coli* strains were isolated from upper small bowel samples of adults with acute undifferentiated diarrhea in Bengal [168,169]. Such strains of *E. coli* produced a heat-labile nondialyzable ammonium sulfate–precipitable enterotoxin [170].

Analogous to the usually short-lived diarrheal illnesses of *E. coli* reported by several workers, a short-lived course of the secretory response to *E. coli* culture filtrates was described [171]. Similar to responses to cholera toxin, secretory responses to *E. coli* were associated with activation of intestinal mucosal adenylate cyclase that paralleled the fluid secretory response [172,173].

The two types of enterotoxins produced by *E. coli* [174–176] have been found to be plasmid-encoded but genetically unlinked. The plasmids encoding LT and ST also encode the colonization factor antigens (CFAs), adhesins required for intestinal colonization, and the regulator that controls CFA expression [144–146,177].

ST causes an immediate and reversible secretory response [150], whereas the effects of LT (e.g., cholera toxin) follow a lag period necessitated by its intracellular site of action [121,122,151]. LT is internalized into target epithelial cells by retrograde vesicular transport. When inside the cytoplasm, the toxin acts by adenosine diphosphate–ribosylation of the $G_{s\alpha}$ signaling protein [112,121]. The resulting activation of adenylate cyclase leads to accumulation of cyclic adenosine monophosphate (cAMP), which activates the CFTR chloride channel. Activation of adenylate cyclase by LT and by cholera toxin is highly promiscuous, occurring in many cell types and resulting in development of nonintestinal tissue culture assay systems such as the Chinese hamster ovary (CHO) cell assay [151] and Y1 adrenal cell assay [152]. The antigenic similarity of LT and cholera toxin and their apparent binding to the monosialoganglioside $GM_1$ have enabled development of ELISAs for detection of LT and cholera toxin [155,178–180].

ST is a much smaller molecule and is distinct antigenically from LT and cholera toxin [151,154,155]. Although it fails to alter cAMP levels, ST increases intracellular intestinal mucosal cyclic guanosine monophosphate (cGMP) concentrations and specifically activates apical plasma membrane–associated intestinal guanylate cyclase [127–129]. Similar to cAMP analogues, cGMP analogues cause intestinal secretion that mimics the response to ST [127]. The receptor for STa responds to an endogenous ligand called guanylin, of which STa is a structural homologue [181]. Because the capacity to produce an enterotoxin may be transmissible between different organisms by a plasmid or even a bacteriophage [144–146], interstrain gene transfer is likely to be responsible for occasional toxigenic non–*E. coli*. Enterotoxigenic *Klebsiella* and *Citrobacter* strains have been associated with diarrhea in a few reports, often in patients coinfected with ETEC [182,183]. Likewise, certain strains of *Salmonella* seem to produce an LT, CHO cell–positive toxin that may play a similar role in the pathogenesis of the watery, noninflammatory diarrhea sometimes seen with *Salmonella enteritidis* infection [184,185].

At least 20 CFAs have been described for human *E. coli* isolates [112,187,188] against which local IgA antibody may be produced. These antigens may potentially be useful in vaccine development. CFAs are proteinaceous hairlike fimbriae that decorate the bacterial surface and serve as a bridge between the bacterium and the epithelial membrane. Veterinary workers first showed that the plasmid-encoded fimbriate K-88 surface antigen was necessary for ETEC to cause disease in piglets [177]. An autosomal dominant allele seems to be responsible for the specific intestinal receptor in piglets. In elegant studies by Gibbons and coworkers [186], the homozygous recessive piglets lacked the receptor for K-88 and were resistant to scours caused by ETEC.

## Epidemiology and Transmission

ETEC are important diarrheal pathogens among infants in developing countries. Breast-feeding seems to provide some protection, however, accounting for the classic association of ETEC with weanling diarrhea. Whether or not this epidemiologic pattern still prevails in impoverished countries is not well understood [149]. ETEC have also been recognized among adults with endemic, cholera-like diarrhea in Calcutta, India, and in Dacca, Bangladesh [121,168], and among travelers to areas such as Mexico and Central Africa [189–191].

The isolation of ETEC is uncommon in sporadic diarrheal illnesses in temperate climates where sanitation facilities are good and where winter viral patterns of diarrhea predominate. ETEC is commonly isolated from infants and children with acute watery summer diarrhea in areas where sanitary facilities are suboptimal [49,182, 191–203], such as Africa [182], Brazil [49,191,197,202, 203], Argentina [193], Bengal [194,195], Mexico [196], and Native American reservations in the southwestern United States [198,199]. In a multicenter study of acute diarrhea in 3640 infants and children in China, India, Mexico, Myanmar, and Pakistan, 16% of cases (versus 5% of 3279 controls) had ETEC [200]. A case-control study from northwestern Spain showed a highly significant association of ETEC with 26.5% of neonatal diarrhea, often acquired in the hospital [201]. Although all types of ETEC are associated with cholera-like, noninflammatory, watery diarrhea in adults in these areas, they probably also constitute the major cause (along with rotaviruses) of dehydrating diarrhea in infants and young children in these areas. In this setting, peaks of illnesses tend to occur in the summer or rainy season, and dehydrating illnesses may be life-threatening, especially in infants and young children [49,197,202]. Humans are probably the major reservoirs for the human strains of ETEC, and contaminated food and water probably constitute the principal vectors [204,205]. Although antitoxic immunity to LT and asymptomatic infection with

LT-producing *E. coli* tend to increase with age, ST is poorly immunogenic, and ST-producing *E. coli* continue to be associated with symptomatic illnesses into adulthood in endemic areas [199,203].

The association of ETEC with outbreaks of diarrhea in newborn nurseries is well documented. Ryder and colleagues [206] isolated ST-producing *E. coli* from 72% of infants with diarrhea, from the environment, and in one instance from an infant's formula during a 7-month period in a prolonged outbreak in a special care nursery in Texas. Another ST-producing *E. coli* outbreak was reported in 1976 by Gross and associates [207] from a maternity hospital in Scotland. ETEC and EPEC were significantly associated with diarrhea among infants younger than 1 year in Bangladesh [208].

An outbreak of diarrhea in a newborn special care nursery that was associated with enterotoxigenic organisms that were not limited to the same serotype or even the same species was reported [209]. The short-lived ETEC, *Klebsiella*, and *Citrobacter* species in this outbreak raised the possibility that each infant's indigenous bowel flora might become transiently toxigenic, possibly by receiving the LT gene from a plasmid or even a bacteriophage.

### Clinical Manifestations

The clinical manifestations of ETEC diarrhea tend to be mild and self-limited except in small or undernourished infants, in whom dehydration may constitute a major threat to life. In many parts of the developing world, acute diarrheal illnesses are the leading recognized causes of death. There is some suggestion that diarrheal illnesses associated with ST-producing ETEC may be particularly severe [195]. Probably the best definition of the clinical manifestations of ETEC infection comes from volunteer studies with adults. Ingestion of $10^8$ to $10^{10}$ human ETEC isolates that produce LT and ST or ST alone resulted in a 30% to 80% attack rate of mild to moderate diarrheal illnesses within 12 to 56 hours that lasted 1 to 3 days [133]. These illnesses, typical for traveler's diarrhea, were manifested by malaise, anorexia, abdominal cramps, and sometimes explosive diarrhea. Nausea and vomiting occur relatively infrequently, and one third of patients may have a low-grade fever. Although illnesses usually resolve spontaneously within 1 to 5 days, they occasionally may persist for 1 week or longer. The diarrhea is noninflammatory, without fecal leukocytes or blood. In outbreaks in infants and neonates, the duration has been in the same range (1 to 11 days), with a mean of approximately 4 days.

### Pathology

As in cholera, the pathologic changes associated with ETEC infection are minimal. From animal experiments in which intestinal loops were infected with these organisms and at a time when the secretory and adenylate cyclase responses were present, there was only a mild discharge of mucus from goblet cells and otherwise no significant pathologic change in the intestinal tract [122]. Unless terminal complications of severe hypotension ensue, ETEC organisms rarely disseminate beyond the intestinal tract. Similar to cholera, ETEC diarrhea is typically limited to being an intraluminal infection.

### Diagnosis

The preliminary diagnosis of ETEC diarrhea can be suspected by the epidemiologic setting and the noninflammatory nature of stool specimens, which reveal few or no leukocytes. Although the ability of *E. coli* to produce enterotoxins may be lost or transmitted to other strains, there is a tendency for the enterotoxin-encoding plasmids to occur among certain predominant serotypes, as shown in Table 11–2 [147]. These serotypes differ from EPEC or invasive serotypes, but their demonstration does not prove that they are enterotoxigenic. The traditional way to identify ETEC is to show the enterotoxin itself by a bioassay, such as tissue culture or ileal loop assays for LT or the suckling mouse assay for ST; ELISA is available for LT, and inhibitory ELISA is available for ST [148].

More recently, detection of enterotoxin-encoding genes has superseded detection of the toxins themselves. Gene probe and PCR technologies are available [113,114]. The presence of *E. coli* encoding the enterotoxins in patients with diarrhea is generally considered diagnostic, although asymptomatic carriage is known to occur [149]. In epidemiologic studies, it is common to test only three colonies per stool for the presence of ETEC, but it is generally considered that testing additional colonies increases diagnostic sensitivity [205,210,211]. A novel method of combining immunomagnetic separation (using antibody-coated magnetic beads) followed by DNA or PCR probing may enhance the sensitivity of screening fecal or food specimens for ETEC or other pathogens [212,213].

### Therapy and Prevention

The mainstay of treatment of any diarrheal illness is rehydration [214]. This principle especially pertains to ETEC diarrhea, which is an intraluminal infection with high output of fluid and electrolytes. The glucose absorptive mechanism remains intact in *E. coli* enterotoxin–induced secretion, much as it does in cholera, a concept that has resulted in the major advance of oral glucose-electrolyte therapy. This regimen can usually provide fully adequate rehydration in infants and children able to tolerate oral fluids, replacing the need for parenteral rehydration in most cases [215,216]. Use of oral glucose-electrolyte therapy is particularly critical in rural areas and developing nations, where early application before dehydration becomes severe may be lifesaving.

The standard World Health Organization solution contains 3.5 g of NaCl, 2.5 g of $NaHCO_3$, 1.5 g of KCl, and 20 g of glucose per 1 L of clean or boiled drinking water [214]. This corresponds to the following concentrations: 90 mmol/L of sodium, 20 mmol/L of potassium, 30 mmol/L of bicarbonate, 80 mmol/L of chloride, and 110 mmol/L of glucose. Various recipes for homemade preparations have been described [217], but unless the cost is prohibitive, the premade standard solution is preferred. Each 4 oz of this solution should be followed by 2 oz of plain water. If there is concern about hypertonicity, especially in small infants in whom a high intake and constant direct supervision of feeding cannot be ensured, the concentration of salt can be reduced [218]. In a multicenter trial involving 447 children in four countries, a reduced osmolality solution with

60 mmol/L of sodium and 84 mmol/L of glucose and a total osmolality of 224 (instead of 311) mOsm/kg was found to reduce stool output by 28% and illness duration by 18% [219]. Commercially available rehydration solutions are increasingly available worldwide [214].

The role of antimicrobial agents in the treatment or prevention of ETEC is controversial. This infection usually resolves within 3 to 5 days in the absence of antibacterial therapy [214]. There is concern about the potential for coexistence of enterotoxigenicity and antibiotic resistance on the same plasmid, and cotransfer of multiple antibiotic resistance and enterotoxigenicity has been well documented [220]. Widespread use of prophylactic antibiotics in areas where antimicrobial resistance is common has the potential for selecting for rather than against enterotoxigenic organisms. The prevention and control of ETEC infections are similar to those discussed under EPEC serotypes. Breast-feeding infants should be encouraged. When antibiotic therapy is desired, cefixime, azithromycin, and, in adults, ciprofloxacin are recommended [221,222], although infants are generally not treated.

## Enteroinvasive *Escherichia coli*

EIEC is similar pathogenetically, epidemiologically, and clinically to shigellosis, although the clinical syndrome associated with EIEC may be milder than that caused by *Shigella* species. EIEC causes diarrhea by means of *Shigella*-like intestinal epithelial invasion (discussed later) [133,134]. The somatic antigens of these invasive strains have been identified and seem to fall into 1 of 10 recognized O groups (see Table 11–2). Most, if not all, of these bacteria share cell wall antigens with one or another of the various *Shigella* serotypes and produce positive reactions with antisera against the cross-reacting antigen [134]. Not all strains of *E. coli* belonging to the 10 serogroups associated with dysentery-like illness are pathogenic, however, because a large (140 MDa) invasive plasmid is also required [223]. Additional biologic tests, including the guinea pig conjunctivitis (Sereny) test or a gene probe for the plasmid, are used to confirm the property of invasiveness [133].

Although an outbreak of food-borne EIEC diarrhea has been well documented among adults who ate an imported cheese [134], little is known about the epidemiology and transmission of this organism, especially in newborns and infants. Whether the infectious dose may be as low as it is for *Shigella* is unknown; however, studies of adult volunteers suggest that attack rates may be lower after ingestion of even larger numbers of EIEC than typical for *Shigella* disease. The outbreak of EIEC diarrhea resulted in a dysentery-like syndrome with an inflammatory exudate in stool and invasion and disruption of colonic mucosa [134].

Descriptions of extensive and severe ileocolitis in infants dying with *E. coli* diarrhea indicate that neonatal disease also can be caused by invasive strains capable of mimicking the pathologic features of shigellosis [224]. The immunofluorescent demonstration of *E. coli* together with an acute inflammatory infiltrate [225] in the intestinal tissue of infants tends to support this impression, although it has been suggested that the organisms may have invaded the bowel wall in the postmortem period [133]. There is still little direct evidence concerning the role of invasive strains of *E. coli* in the cause of neonatal diarrhea [191]. The infrequency with which newborns manifest a dysentery-like syndrome makes it unlikely that this pathogen is responsible for a very large proportion of the diarrheal disease that occurs during the first month of life.

The diagnosis should be suspected in infants who have an inflammatory diarrhea as evidenced by fecal polymorphonuclear neutrophils or bloody dysenteric syndromes from whom no other invasive pathogens, such as *Campylobacter*, *Shigella*, *Salmonella*, *Vibrio*, or *Yersinia*, can be isolated. In this instance, it may be appropriate to have the fecal *E. coli* isolated and serotyped or tested for invasiveness in the Sereny test. Plasmid pattern analysis and chromosomal restriction endonuclease digestion pattern analysis by pulsed-field gel electrophoresis have been used to evaluate strains involved in outbreaks [226]. The management and prevention of EIEC diarrhea should be similar to management and prevention of acute *Shigella* or other *E. coli* enteric infections.

## Enteropathogenic *Escherichia coli*: Classic Serotypes

EPEC is a classic cause of severe infant diarrhea in industrialized countries, although its incidence has diminished dramatically in recent years. The serologic distinction of *E. coli* strains associated with epidemic and sporadic infantile diarrhea was first suggested by Goldschmidt in 1933[227] and confirmed by Dulaney and Michelson in 1935 [351]. These researchers found that certain strains of *E. coli* associated with institutional outbreaks of diarrhea would agglutinate with sera from diarrhea patients in other outbreaks. In 1943, Bray [228] isolated a serologically homogeneous strain of *E. coli* (subsequently identified as serogroup O111) from 95% of infants with summer diarrhea in England. He subsequently summarized a larger experience with this organism, isolated from only 4% of asymptomatic controls, but from 88% of infants with diarrhea, one half of which was hospital acquired [229]. This strain (initially called *E. coli-gomez* by Varela in 1946) also was associated with infantile diarrhea in Mexico [230]. A second type of *E. coli* (called beta by Giles in 1948 and subsequently identified as O55) was associated with an outbreak of infantile diarrhea in Aberdeen, Scotland [231,232].

An elaborate serotyping system for certain *E. coli* strains that were clearly associated with infantile diarrhea developed from this early work primarily with epidemic diarrhea in infants [233–235]. These strains first were called enteropathogenic *E. coli* by Neter and colleagues [236] in 1955, and the association with particular serotypes can still be observed [237]. As shown in Table 11–1, these organisms are distinct from the enterotoxigenic or enteroinvasive organisms or organisms that inhabit the normal GI tract. They exhibit localized adherence to HEp-2 cells, a phenotype that has been suggested to be useful for diagnosis and pathogenesis research [135].

### *Epidemiology and Transmission*

EPEC is now an important cause of diarrhea in infants in developing or transitional countries [112,238–240]. Outbreaks have become rare in the United States and other

industrialized countries, but they still occur [241]. Some researchers have attributed the rare recognition of illness in part to the declining severity of diarrheal disease caused by EPEC within the past 30 years, resulting in fewer cultures being obtained from infants with relatively mild symptoms [112,242]. Several other variables influence the apparent incidence of this disease in the community, however. A problem arises with false-positive EPEC identification on the basis of the nonspecific cross-reactions seen with improper shortening of the serotyping procedure [243,244]. Because of their complexity and relatively low yield, neither slide agglutination nor HEp-2 cell adherence or DNA probe tests are provided as part of the routine identification of enteric pathogens by most clinical bacteriology laboratories. Failure to recognize the presence of EPEC in fecal specimens is the inevitable consequence.

The apparent incidence of EPEC gastroenteritis also varies with the epidemiologic circumstances under which stool cultures are obtained. The prevalence of enteropathogenic strains is higher among infants from whom cultures are obtained during a community epidemic compared with cultures obtained during sporadic diarrheal disease. Neither cultures obtained during a community epidemic nor cultures obtained during sporadic diarrheal disease reflect the incidence of EPEC infection among infants involved in a nursery outbreak or hospital epidemic.

EPEC gastroenteritis is a worldwide problem, and socioeconomic conditions play a significant role in determining the incidence of this disease in different populations [245]. It is unusual for newborn infants born in a rural environment to manifest diarrheal disease caused by EPEC; most infections of the GI tract in these infants occur after the first 6 months of life [9,246]. Conversely, among infants born in large cities, the attack rate of EPEC is high during the first 3 months of life. This age distribution reflects in large part the frequency with which EPEC causes cross-infection outbreaks among nursery populations [207,247–254]; however, a predominance of EPEC in infants in the first 3 months of life has also been described in community epidemics [255–257] and among sporadic cases of diarrhea acquired outside the hospital [258–264]. The disparity in the incidence of neonatal EPEC infection between rural and urban populations has been ascribed to two factors: the trend away from breast-feeding among mothers in industrialized societies and the crowding together of susceptible newborns in nurseries in countries in which hospital deliveries predominate over home deliveries [9,246,265]. Although the predominant serogroup can vary from year to year,* the same strains have been prevalent during the past 40 years in Great Britain [268], Puerto Rico [269], Guatemala [9], Panama [223], Israel [264], Newfoundland [257], Indonesia [261], Thailand [270], Uganda [271], and South Africa [272].

When living conditions are poor and overcrowding of susceptible infants exists, there is an increase in the incidence of neonatal diarrhea in general [273] and EPEC gastroenteritis in particular [232,255,274]. A higher incidence of asymptomatic family carriers is likewise found in such situations [255,256].

Newborns can acquire EPEC during the first days of life by one of several routes: (1) organisms from the mother ingested at the time of birth; (2) bacteria from other infants or toddlers with diarrheal disease or from asymptomatic adults colonized with the organism, commonly transmitted on the hands of nursery personnel or parents; (3) airborne or droplet infection; (4) fomites; or (5) organisms present in formulas or solid food supplements [275]. Only the first two routes have been shown conclusively to be of significance in the transmission of disease or the propagation of epidemics.

Most neonates acquire EPEC at the time of delivery through ingestion of organisms residing in the maternal birth canal or rectum. Stool cultures taken from women before, during, or shortly after delivery have shown that 10% to 15% carry EPEC at some time during this period [99,100,102,276,277]. Use of fluorescent antibody techniques [277] or cultures during a community outbreak of EPEC gastroenteritis [102] revealed twice this number of persons excreting the organism. Virtually none of the women carrying pathogenic strains of *E. coli* had symptoms referable to the GI tract.

Many mothers whose stools contain EPEC transmit these organisms to their infants [99,102], resulting in an asymptomatic infection rate of 2% to 5% among newborns cultured at random in nursery surveys [99,100,207,278]. These results must be considered conservative and are probably an artifact of the sampling technique. One study using 150 O antisera to identify as many *E. coli* as possible in fecal cultures showed a correlation between the coliform flora in 66% of mother-infant pairs [279]. Of particular interest was the observation that the O groups of *E. coli* isolated from the infants' mucus immediately after delivery correlated with those subsequently recovered from their stools, supporting the contention that these organisms were acquired orally at the time of birth. In mothers whose stools contained the same O group as their offspring, the mean time from rupture of membranes to delivery was about 2 hours longer than in mothers whose infants did not acquire the same serogroups, suggesting that ascending colonization before birth also can play a role in determining the newborn's fecal flora.

The contours of the epidemiologic curves in nursery [255,280–285] and community [255–257] outbreaks are in keeping with a contact mode of spread. Transmission of organisms from infant to infant occurs by the fecal-oral route in almost all cases, most likely via the hands of individuals attending to their care [100,283,285,286]. Ill infants represent the greatest risk to individuals around them because of the large numbers of organisms found in their stools [287–290] and vomitus [291–293]. Cross-infection has also been initiated by infants who were healthy at the time of nursery admission [280,288,294–296].

A newborn exposed to EPEC is likely to acquire enteric infection whenever contact with a person excreting the organism is intimate and prolonged, as in a hospital or family setting. Stool culture surveys taken during outbreaks have shown that 20% to 50% of term neonates

*References [256,259,260,263,266,267].

residing in the nursery carry EPEC in their intestinal tracts [118,247,248,251]. Despite descriptions of nursery outbreaks in which virtually every neonate or low birth weight infant became infected [278,280,297], there is ample evidence that exposure to pathogenic strains of *E. coli* does not result in greater likelihood of illness for premature infants than for term infants [277,288,295,298]. Any increased prevalence of cross-infections that may exist among premature infants can be explained more readily by their prolonged hospital stays, increased handling, and clustering of infants born in different institutions than by a particular susceptibility to EPEC based on immature defense mechanisms.

The most extensive studies on the epidemiology of gastroenteritis related to *E. coli* have dealt with events that occurred during outbreaks in newborn nurseries. Investigations of this sort frequently regard the epidemic as an isolated phenomenon and ignore the strong interdependence that exists between community-acquired and hospital-acquired illness [296,299,300]. The direction of spread is most often from the reservoir of disease within the community to the hospital. When the original source of a nursery outbreak can be established, frequently it is an infant born of a carrier mother who recently acquired EPEC infection from a toddler living in the home. Cross-infection epidemics also can be initiated by infected newborns that have been admitted directly into a clean nursery unit from the surrounding district [286,288,301] or have been transferred from a nearby hospital [294,296,302].

After a nursery epidemic has begun, it generally follows one of two major patterns. Some epidemics are explosive, with rapid involvement of all susceptible infants and a duration that seldom exceeds 2 or 3 months [280,281,292,303]. The case-fatality rate in these epidemics may be very high. Other nursery outbreaks have an insidious onset with a few mild, unrecognized cases; the patients may not even develop illness until after discharge from the hospital. During the next few days to weeks, neonates with an increased number of loose stools are reported by the nurses; shortly thereafter, the appearance of the first severely ill infants makes it apparent that an epidemic has begun. Unless oral antimicrobial therapy is instituted (see "Therapy"), nursery outbreaks such as these may continue for months [282–285] or years [286], with cycles of illness followed by periods of relative quiescence. This pattern can be caused by multiple strains (of different phage or antibiogram types) sequentially introduced into the nursery [294,304,305].

The nursery can be a source of infection for the community. The release of infants who are in the incubation stages of illness or are convalescent carriers about to relapse may lead to secondary cases of diarrheal disease among young siblings living in widely scattered areas [255,256,260]. These children further disseminate infection to neighboring households, involving playmates of their own age, young infants, and mothers [255,256,259]. As the sickest of these contact cases are admitted to different hospitals, they contaminate new susceptible persons, completing the cycle and compounding the outbreak. This feedback mechanism has proved to be a means of spreading infantile gastroenteritis through entire cities [255,256,259], counties [256,301,306], and provinces [257]. One major epidemic of diarrhea related to EPEC O111:B4 that occurred in the metropolitan Chicago and northwestern Indiana region during the winter of 1961 involved more than 1300 children and 29 community hospitals during a period of 9 months [257,307]. Almost all of the patients were younger than 2 years, and 10% were younger than 1 month, producing an age-specific attack rate of nearly 4% of neonates in the community. The importance of the hospital as a source of cross-infection in this epidemic was shown through interviews with patients' families, indicating that a minimum of 40% of infants had direct or indirect contact with a hospital shortly before the onset of illness.

It has been suggested, but not proven, that asymptomatic carriers of EPEC in close contact with a newborn infant, such as nursery personnel or family members, might play an important role in the transmission of the bacterium [296,300,308]. Stool culture surveys have shown that at any one time about 1% of adults [259,309] and 1% to 5% of young children [247,255,260] who are free of illness harbor EPEC strains. Higher percentages have been recorded during community epidemics [255,260]. Because this intestinal carriage is transitory [255,296], the number of individuals who excrete EPEC at one time or another during the year is far higher than the 1% figure recorded for single specimens [296,309].

Nursery personnel feed, bathe, and diaper a constantly changing population of newborns, about 2% to 5% of whom excrete EPEC [255,296]. Despite this constant exposure, intestinal carriage among nursery workers is surprisingly low. Even during outbreaks of diarrheal illness, when dissemination of organisms is most intense, less than 5% of the hospital personnel in direct contact with infected neonates are themselves excreting pathogenic strains of *E. coli* [307,310,311].

Although asymptomatic adult carriers generally excrete fewer organisms than patients with acute illness do [288], large numbers of pathogenic bacteria may nevertheless exist in their stools [259,290]. No nursery outbreak and few family cases [257] have been traced to a symptomless carrier, however. Instead, passive transfer of bacteria from infant to infant by the hands of personnel seems to be of primary importance in these outbreaks.

EPEC can be recovered from the throat or nose of 5% to 80% of infants with diarrheal illness [291,310,311] and from about 1% of asymptomatic infants [249,260]. The throat and nasal mucosa may represent a portal of entry or a source of transmission for EPEC. Environmental studies have shown that EPEC is distributed readily and widely in the vicinity of an infant with active diarrheal disease, often within 1 day of admission to the ward [249,312]. Massive numbers of organisms are shed in the diarrheal stool or vomitus of infected infants [266,312]. *E. coli* organisms may survive 2 to 4 weeks in dust [260,312] and can be found in the nursery air when the bedding or diapers of infected infants are disturbed during routine nursing procedures [260,312] or on floors; walls; cupboards; and nursery equipment such as scales, hand towels, bassinets, incubators, and oxygen tents of other infants [102,260,283]. Documentation of the presence of EPEC in nursery air and dust does not by itself establish the importance of this route as a source of

cross-infection. One study presented evidence of the respiratory transmission of EPEC; however, even in the cases described, the investigators pointed out that fecal-oral transmission could not be completely ruled out [255]. Additional clinical and experimental data are required to clarify the significance of droplet and environmental infection.

Coliform organisms have also been isolated in significant numbers from human milk [60,313,314], prebottled infant formulas [315], and formulas prepared in the home [308]. EPEC in particular has been found in stool cultures obtained from donors of human milk and workers in a nursery formula room [276]. In one instance, EPEC O111:B4 was isolated from a donor, and subsequently the same serogroup was recovered in massive amounts in almost pure culture from her milk [276]. Pathogenic strains of *E. coli* have also been isolated from raw cow's milk [316] and from drinking water [317]. Likewise, EPEC has been isolated from flies during an epidemic, but this fact has not been shown to be of epidemiologic significance [228,237].

### Pathogenesis

Infection of a newborn infant with EPEC occurs exclusively by the oral route. Attempts to induce disease in adult volunteers by rectal instillation of infected material have been unsuccessful [112]. There are no reports of disease occurring after transplacental invasion of the fetal bloodstream by enteropathogenic or nonenteropathogenic strains of *E. coli*. Ascending intrauterine infection after prolonged rupture of the membranes has been reported only once; the neonate in this case had only mild diarrhea [100].

Bacterial cultures of the meconium and feces of newborns indicate that enteropathogenic strains of *E. coli* can effectively colonize the intestinal tract in the first days of life [99–102]. Although *E. coli* may disappear completely from stools of breast-fed infants during the ensuing weeks, this disappearance is believed to be related to factors present in the human milk rather than the gastric secretions [9,318,319]. The use of breast-feeding or expressed human milk has even been effective in terminating nursery epidemics caused by EPEC O111:B4, probably by reducing the incidence of cross-infections among infants [319,320]. Although dose-effect studies have not been performed among newborns, severe diarrhea has occurred after ingestion of $10^8$ EPEC organisms by very young infants [321,322]. The high incidence of cross-infection outbreaks in newborn nurseries suggests that a far lower inoculum can often affect spread in this setting.

The role of circulating immunity in the prevention of GI tract disease related to EPEC has not been clearly established. Virtually 100% of maternal sera have been found to contain hemagglutinating [236,323,324], bactericidal [321,325], or bacteriostatic [296,326] antibodies against EPEC. The passive transfer of these antibodies across the placenta is extremely inefficient. Titers in blood of newborn infants are, on average, 4 to 100 times lower than titers in the corresponding maternal sera. Group-specific hemagglutinating antibodies against the O antigen of EPEC are present in 10% to 20% of cord blood samples [236,323,324], whereas bactericidal [323,327] or bacteriostatic [327] activity against these organisms can be found much more frequently. Tests for bacterial agglutination, which are relatively insensitive, are positive in only a small percentage of neonates [236,327].

The importance of circulating antibodies in the susceptibility of infants to EPEC infection is unknown. Experiments with suckling mice have failed to show any effect of humoral immunity on the establishment or course of duration of intestinal colonization with *E. coli* O127 in mothers or their infants [328]. Similar observations have been made in epidemiologic studies among premature human infants using enteropathogenic (O127:B8) [325] and nonenteropathogenic (O4:H5) [285] strains of *E. coli* as the indicator organisms. In a cohort of 63 mothers and their infants followed from birth to 3 months old, Cooper and associates [99] showed a far higher incidence of clinical EPEC disease in infants of EPEC-negative mothers than in infants born of mothers with EPEC isolated from stool cultures. This finding suggests the possibility that mothers harboring EPEC in their GI tracts transfer specific antibodies to their infants that confer some protection during the first weeks of life.

Protection against enteric infections in humans often correlates more closely with levels of local secretory rather than serum antibodies. Although it is known that colonization of newborns with *E. coli* leads to the production of coproantibodies against the ingested organisms [329,330], the clinical significance of this intestinal immunity is uncertain. The previously mentioned experiment with mice showed no effect of active intestinal immunity on enteric colonization [328]. In human infants, the frequency of bacteriologic and clinical relapse related to EPEC of the same serotype [280,281,295] and the capacity of one strain of EPEC to superinfect a patient already harboring a different strain [264,274,284] also cast some doubt on the ability of mucosal antibodies to inhibit or alter the course of intestinal infection. Studies of the protective effects of orally administered EPEC vaccines could help to resolve these questions [265].

The mechanism by which EPEC causes diarrhea involves a complex array of plasmid and chromosomally encoded traits. EPEC serotypes do not make one of the recognized enterotoxins (LT or ST) as usually measured in tissue culture or animal models [331–335], and these serotypes do not cause a typical invasive colitis or produce a positive Sereny test result [330,331]. Only uncommonly do EPEC strains invade the bloodstream or disseminate [304]. Nevertheless, EPEC strains that test negative in these tests are capable of causing diarrhea; inocula of $10^{10}$ *E. coli* O142 or O127 organisms caused diarrhea in 8 of 10 adult volunteers [335].

Some EPEC strains may secrete weak enterotoxins [336,337], but the consensus opinion is that the attaching-and-effacing lesion constitutes the critical virulence phenotype for secretory disease [112,137]. Clinical pathologic reports reveal the characteristic attaching-and-effacing lesion in the small intestine of infected infants [338]. The lesion is manifested by intimate (about 10 nm) apposition of the EPEC to the plasma membrane of the enterocytes, with dissolution of the normal brush border and rearrangement of the cytoskeleton [137,338].

In some instances, the bacteria are observed to rise up on pedestal-like structures, which are diagnostic of the infection [137]. Villus blunting, crypt hypertrophy, histiocytic infiltration in the lamina propria, and a reduction in the brush border enzymes may also be observed [338,339].

Two major EPEC virulence factors have been described; strains with both factors are designated as typical EPEC [112,115,340]. One such factor is the locus of enterocyte effacement (LEE), a type III secretion system encoded by the LEE chromosomal pathogenicity island [341–343]. The LEE secretion apparatus injects proteins directly from the cytoplasm of the infecting bacterium into the cytoplasm of the target enterocytes [342]. The injected proteins constitute cytoskeletal toxins, which together elicit the close apposition of the bacterium to the cell, cause the effacement of microvilli, and most likely give rise to the net secretory state [112,115,137]. One critical secreted protein, called translocated intimin receptor (Tir) [136], inserts into the plasma membrane of the epithelial cell, where it serves as the receptor for a LEE-encoded EPEC outer membrane protein called intimin [137]. Animals infected with attaching-and-effacing pathogens mount antibody responses to intimin and Tir [344], and both are considered potential vaccine immunogens. The lack of protection from EPEC reinfection suggests that natural antibody responses to Tir and intimin are not protective.

The second major virulence factor of typical EPEC is the bundle-forming pilus (BFP) [345], which is encoded on a partially conserved 60-MDa virulence plasmid called EPEC adherence factor (EAF) [346]. BFP, a member of the type IV pilus family, mediates aggregation of the bacteria to each other and probably to enterocytes themselves, facilitating mucosal colonization [347]. A BFP mutant was shown to be attenuated in adult volunteers [348]. More recent epidemiologic data suggest that some virulent EPEC may lack the BFP; such strains are termed *atypical EPEC* [349,350]. These strains are not of the characteristic EPEC serotypes, and means to distinguish them clinically and microbiologically are unavailable as of this writing.

### Pathology

The principal pathologic lesion in EPEC infection is the attaching-and-effacing lesion, manifest by electron microscopy, but not light microscopy. In chronic cases, villus blunting, crypt hypertrophy, histiocytic infiltration of the lamina propria, and reduced brush border enzymes may be seen. Rothbaum and colleagues [338] described similar findings with dissolution of the glycocalyx and flattened microvilli with the nontoxigenic EPEC strain O119:B14. A wide range of pathologic findings has been reported in infants dying with EPEC gastroenteritis. Most newborns dying with diarrheal disease caused by EPEC show no morphologic changes of the GI tract by gross or microscopic examination of tissues [227,351]. Bray [228] described such "meager" changes in the intestinal tract that "the impression received was that the term gastroenteritis is incorrect." At the other extreme, extensive and severe involvement of the intestinal tract, although distinctly unusual among neonates with EPEC diarrhea, has been discussed in several reviews of the pathologic anatomy of this disease [264,334,352]. Changes virtually identical to the changes found in infants dying with necrotizing enterocolitis have been reported [352]. Drucker and coworkers [334] found that among 17 infants with EPEC diarrhea who were dying, "intestinal gangrene, and/or perforation, and/or peritonitis were present in five, and intestinal pneumatosis in five."

The reasons for such wide discrepancies in EPEC disease pathology are unclear. The severity of intestinal lesions at the time of death does not correlate with the birth weight of the patient, the age of onset of illness, the serogroup of the infecting strain, or the prior administration of oral or systemic antimicrobial agents. The suggestion that the intensity of inflammatory changes may depend on the duration of the diarrhea [334] cannot be corroborated in autopsy studies [232,280,353] or small intestinal biopsy specimens [354,355]. It is difficult to reconcile such a thesis with the observation that a wide range of intestinal findings can be seen at autopsy among newborns infected by a single serotype of EPEC during an epidemic. The nonspecific pathologic picture described by some researchers includes capillary congestion and edema of the bowel wall and an increase in the number of eosinophils, plasma cells, macrophages, and mononuclear cells in the mucosa and submucosa [278,334,353]. Villous patterns are generally well preserved, although some flattening and broadening of the villi are seen in more severe cases. Almost complete absence of villi and failure of regeneration of small bowel mucosa have been reported in an extreme case [356]. Edema in and around the myenteric plexuses of Auerbach, a common associated finding, may cause the GI tract dilation often seen at autopsy in infants with EPEC infections [264,353,357]. Generally, the distal small intestine shows the most marked alterations; however, the reported pathologic findings may be found at all levels of the intestinal tract.

Several complications of EPEC infection have been reported. Candidal esophagitis accounted for significant morbidity in two series collected before [351] and during [264] the antibiotic era. Oral thrush has been seen in 50% of EPEC-infected infants treated with oral or systemic antibiotics [262,280,353]. Some degree of fatty metamorphosis of the liver has been reported by several investigators [232,351,353]; however, these changes are nonspecific and probably result from the poor caloric intake associated with persistent diarrhea or vomiting. Some degree of bronchopneumonia, probably a terminal event in most cases, exists in a large proportion of newborns dying of EPEC infection [232,351,357]. In one reported series of infant cases, EPEC was shown by immunofluorescent staining in the bronchi, alveoli, and interalveolar septa.

Mesenteric lymph nodes are often swollen and congested with reactive germinal centers in the lymphoid follicles [232,278,309]. Severe lymphoid depletion, unrelated to the duration or severity of the antecedent illness, also has been described [301]. The kidneys frequently show tubular epithelial toxic changes. Various degrees of tubular degeneration and cloudy swelling of convoluted tubules are common findings [232,301,353]. Renal vein

thrombosis or cortical necrosis may be observed in infants with disseminated intravascular coagulation in the terminal phases of the illness. The heart is grossly normal in most instances, but may show minimal vacuolar changes of nonspecific toxic myocarditis on microscopic examination [353,357]. Candidal abscesses of the heart [357] and kidneys [301,353,357] have been described. With the exception of mild congestion of the pia arachnoid vessels and some edema of the meninges, examination of the central nervous system reveals few changes [232,278].

### *Clinical Manifestations*

Exposure of newborns to EPEC may be followed by one of several possible consequences: no infection, infection without illness, illness with gastroenteritis of variable severity and duration, and, rarely, septicemia with or without metastatic foci of infection accompanying gastroenteritis. When infants are exposed to EPEC, many become colonized as temporary stool [99,102,248] or pharyngeal [255] carriers with no signs of clinical disease. Although Laurell [358] showed that the percentage of asymptomatic infections increases steadily as age increases, this observation has not been confirmed by other investigators [231,359]. Similarly, the suggestion that prematurity per se is associated with a low incidence of inapparent EPEC infection has been documented in several clinical studies [278,280,281], but refuted in others [269,295].

Most neonates who acquire infection with EPEC eventually show some clinical evidence of gastroenteritis. The incubation period is quite variable. Its duration has been calculated mostly from evidence in outbreaks in newborn nurseries, where the time of first exposure can be clearly defined in terms of birth or admission dates. In these circumstances, almost all infants show signs of illness 2 to 12 days after exposure, and most cases show signs within the first 7 days [232,248,280]. In some naturally acquired [99,100] and experimental [322] infections with heavy exposure, the incubation period may be only 24 hours; the stated upper limit is 20 days [249,360]. The first positive stool culture and the earliest recognizable clinical signs of disease occur simultaneously in most infants [280,282], although colonization may precede symptoms by 7 to 14 days [281,282,361].

The gastroenteritis associated with EPEC infection in the newborn is notable for its marked variation in clinical pattern. Clinical manifestations vary from mild illness manifest only by transient anorexia and failure to gain weight to a sudden explosive fulminating diarrhea causing death within 12 hours of onset. Prematurity, underlying disease, and congenital anomalies often are associated with the more severe forms of illness [231,250,362,363]. Experienced clinicians have observed that the severity of EPEC gastroenteritis has declined markedly during the past 3 decades [242]. The onset of illness usually is insidious, with vague signs of reluctance to feed, lethargy, spitting up of formula, mild abdominal distention, or weight loss that may occur for 1 or 2 days before the first loose stool is passed. Diarrhea usually begins abruptly. It may be continuous and violent, or in milder infections, it may run an intermittent course with 1 or more days of normal stools followed by 1 or more days of diarrhea. Emesis sometimes is a prominent and persistent early finding. Stools are loose and bright yellow initially, later becoming watery, mucoid, and green. Flecks or streaks of blood, which are commonly seen with enterocolitis caused by *Salmonella*, *Campylobacter*, or *Shigella*, are rarely a feature of EPEC diarrheal disease.

A characteristic seminal smell may pervade the environment of infants infected with EPEC O111:B34 [249,278,364], and an odor variously described as "pungent," "musty," or "fetid" often surrounds patients excreting other strains in their stools [248,272]. Because the buttocks are repeatedly covered with liquid stools, excoriation of the perianal skin can be an early and persistent problem. Fever is an inconstant feature, and when it occurs, the patient's temperature rarely is greater than 39° C (>102.2° F). Convulsions occur infrequently; their occurrence should alert the clinician to the possible presence of electrolyte disturbances, particularly hypernatremia. Prolonged hematochezia, distention, edema, and jaundice are ominous signs and suggest an unfavorable prognosis [232,257,301].

Most infants receiving antimicrobial agents orally show a cessation of diarrhea, tolerate oral feedings, and resume weight gain within 3 to 7 days after therapy has been started [259,262]. Infants with mild illness who receive no treatment can continue to have intermittent loose stools for 1 to 3 weeks. In one outbreak related to EPEC O142:K86, more than one third of untreated or inappropriately treated infants had diarrhea for more than 14 days in the absence of a recognized enteric pathogen on repeated culturing [283]. Recurrence of diarrhea and vomiting after a period of initial improvement is characteristic of EPEC enteritis [207,256,257].

Although seen most often in newborns who have been treated inadequately or not treated at all, clinical relapses also occur after appropriate therapy. Occasionally, the signs of illness during a relapse can be more severe than those accompanying the initial attack of illness [232,249,301]. Not all clinical relapses result from persistent infection. Many relapses, particularly relapses that consistently follow attempts at reinstitution of formula feedings [278,281], are caused by disaccharide intolerance, rather than bacterial proliferation. Intestinal superinfections, caused by another serotype of EPEC [299,364,365] or by completely different enteric pathogens, such as *Salmonella* or *Shigella* [262], also can delay the resolution of symptoms. Rarely, infants have a "relapse" caused by an organism from the same O group as the original strain but differing in its H antigen. Unless complete serotyping is performed on all EPEC isolates, such an event easily could be dismissed as being a recurrence rather than a superinfection with a new organism [274,284].

Antimicrobial agents to which the infecting organisms are susceptible often may not eradicate EPEC [262,281,283], which may persist for weeks [280,299,361] or months [366] after the acute illness has subsided. Although reinfection cannot always be excluded, many infants are discharged from the hospital with positive rectal cultures [248,250]. Dehydration is the most common and serious complication of gastroenteritis caused by EPEC or a toxin-producing *E. coli*. Virtually all deaths directly

attributable to the intestinal infection are caused by disturbances in fluids and electrolytes. When stools are frequent in number, large in volume, and violent in release, as they often are in severe infections with abrupt onset, a neonate can lose 15% of body weight in a few hours [249,292]. Rarely, fluid excretion into the lumen of the bowel proceeds so rapidly that reduction of circulating blood volume and shock may intervene before passage of a single loose stool [278]. Before the discovery of the etiologic agent, epidemic diarrhea of the newborn was also known by the term *cholera infantum*.

Mild disease, particularly when aggravated by poor fluid intake, can lead to a subtle but serious deterioration of an infant's metabolic status. Sometimes, a week or more of illness elapses before it becomes apparent that an infant with borderline acidosis and dehydration who seemed to be responding to oral fluids alone requires parenteral therapy for improvement [288]. It is incumbent on the clinician caring for small infants with gastroenteritis to follow them closely, with particular attention to serial weights, until full recovery can be confirmed.

Few other complications, with the possible exception of aspiration pneumonia, are directly related to EPEC gastroenteritis. Protracted diarrhea and nutritional failure may occur as a consequence of functional damage to the small intestinal mucosa, with secondary intolerance to dietary sugars [281,356]. Necrotizing enterocolitis, which occasionally results in perforation of the bowel and peritonitis, has not been causally related to infection with EPEC [264,280,282]. A review of most of the large clinical series describing EPEC disease in infants ranging in age from newborn to 2 years revealed only three proven instances of bacteremia [281,294], one possible urinary tract infection [281], and one documented case of meningitis in an infant of unspecified age [367]. Focal infections among neonates were limited to several cases of otitis media [264,278] and a subcutaneous abscess [310] from which EPEC was isolated. Additional complications include interstitial pneumonia [334], GI bleeding with or without disseminated intravascular coagulation [352,368], and methemoglobinemia caused by a mutant of EPEC O127:B8 that was capable of generating large quantities of nitrite from proteins present in the GI tract [369].

## Diagnosis

The gold standard of EPEC diagnostics is identification in the stool of *E. coli* carrying genes for BFP and LEE. Identification of these genes can be accomplished by molecular methods (discussed later), but lack of access to these methods has led many laboratories to rely on surrogate markers, such as serotyping [31]. Classic EPEC has been recovered from the vomitus, stool, or bowel contents of infected newborns. Isolation from bile [250] and the upper respiratory tract [99,255,256] has been described in instances in which a specific search has been made. Less commonly, EPEC is isolated from ascitic fluid [269] or purulent exudates [227,232,310]; occasionally, the organism has been recovered from blood cultures [281,294], urine [281], and cerebrospinal fluid.

Stool cultures generally are more reliable than rectal swabs in detecting the presence of enteric pathogens, although a properly obtained swab should be adequate to show EPEC in most cases [234,312,370]. Specimens should be obtained as early in the course of the illness as possible because organisms are present in virtually pure culture during the acute phase of the enteritis, but diminish in numbers during convalescence. Because of the preponderance of EPEC in diarrheal stools, two cultures are adequate for isolation of these pathogens in almost all cases of active disease. Studies using fluorescent antibody methods for identification of EPEC in stool specimens have shown that during the incubation period of the illness, during convalescence, and among asymptomatic carriers of EPEC, organisms can be excreted in such small numbers that they escape detection by standard bacteriologic methods in a significant proportion of infants [262,371,372]. Three to 10 specimens may be required to detect EPEC using methods that identify individual EPEC isolates in the stool [99,363].

After a stool specimen is received, it should be plated as quickly as possible onto noninhibiting media or placed in a preservative medium if it is to be held for longer periods. Deep freezing of specimens preserves viable EPEC when a prolonged delay in isolation is necessary [235]. No selective media, biochemical reactions, or colonial variations permit differentiation of pathogenic and nonpathogenic strains. Certain features may aid in the recognition of two important serogroups. Cultures of serogroups O111:B4 and O55:B5, in contrast to many other coliforms, are sticky or stringy when picked with a wire loop and are rarely hemolytic on blood agar [234,236], whereas O111:B4 colonies emit a distinctive evanescent odor commonly described as "seminal." [231,351] This unusual odor first led Bray [364] to suspect that specific strains of *E. coli* might be responsible for infantile gastroenteritis.

Simpler than molecular detection, serotyping can be used to identify likely EPEC strains, especially in outbreaks [233]. *E. coli*, similar to other Enterobacteriaceae members, possesses cell wall somatic antigens (O), envelope or capsular antigens (K), and, if motile, flagellar antigens (H). Many O groups may be divided further into two or more subgroups (a, b, c), and the K antigens are divisible into at least three varieties (B, L, A) on the basis of their physical behavior. Organisms that do not possess flagellar antigens are nonmotile (designated NM). The EPEC B capsular surface antigen prevents agglutination by antibodies directed against the underlying O antigen. Heating at 100° C for 1 hour inactivates the agglutinability and antigenicity of the B antigen.

Slide agglutination tests with polyvalent O or OB antiserum may be performed on suspensions of colonies typical of *E. coli* that have been isolated from infants with diarrhea, especially in nursery outbreaks. Because of numerous false-positive "cross-reactions," the O and K (or B) type must be confirmed by titration with the specific antisera [244]. Its presence alone does not prove that EPEC is the cause of diarrhea in an individual patient. Mixed cultures with two or three serotypes of EPEC have been shown in 1% to 10% of patients [261,262,368]. This need not mean that both or all three serotypes are

causative agents. Secondary infection with hospital-acquired strains can occur during convalescence [189,297,299,373], and some infants may have been asymptomatic carriers of one serotype at the time that another produced diarrheal disease.

A similar explanation may pertain to mixed infections with EPEC and *Salmonella* or *Shigella* [234,237,374]. Nelson [262] reported the presence of these pathogens in combination with EPEC in 14% of infants who were cultured as part of an antibiotic therapy trial. *Salmonella* and *Shigella* that had not been identified on cultures obtained at admission were isolated only after institution of oral therapy with neomycin. Nelson also [262] postulated that the alteration in bowel flora brought about by the neomycin facilitated the growth of these organisms, which had previously been suppressed and obscured by coliform overgrowth. It is important to seek all enteric pathogens in primary and follow-up cultures of infantile diarrhea, particularly when the specimen originates from a patient in a newborn nursery or infants' ward.

Although EPEC gastroenteritis was previously considered to be synonymous with "summer diarrhea," community outbreaks have occurred as frequently, if not more frequently, in the colder seasons [150,177,375]. It has been suggested that the increased incidence at that time of year might be related to the heightened chance of contact between infants and toddlers that is bound to occur when children remain indoors in close contact [310]. Nursery epidemics, which depend on the chance introduction and dissemination of EPEC within a relatively homogeneous population and stable environment, exhibit no seasonal prevalence. Average relative humidity, temperature, and hours of daylight have no significant effect in determining whether an outbreak follows the introduction of enteropathogenic strains of *E. coli* into a ward of infants [260].

There are no clinical studies of the variations in peripheral leukocyte count, urine, or cerebrospinal fluid in neonatal enteritis caused by EPEC. Microscopic examination of stools of infants with acute diarrheal illness caused by these organisms usually has revealed an absence of fecal polymorphonuclear leukocytes [231,272,335,376], although data on fecal lactoferrin in human volunteers suggest that an inflammatory process may be important in EPEC diarrhea [377,378]. Stool pH can be neutral, acid, or alkaline [76,359]. Serologic methods have not proved to be useful in attempting to establish a retrospective diagnosis of EPEC infection in neonates. Increasing or significantly elevated agglutinin titers rarely could be shown in early investigations [232,248,351]; hemagglutinating antibodies showed a significant response in only 10% to 20% of cases [262,313].

Fluorescent antibody techniques have shown promise for preliminary identification of EPEC in acute infantile diarrhea. This method is specific, with few false-positive results, and it is more sensitive than conventional plating and isolation techniques [298,378,379]. The rapidity with which determinations can be performed makes them ideally suited for screening ill infants and possible carriers in determining the extent and progression of a nursery [288,298] or community [255,307] outbreak. Because immunofluorescence does not depend on the viability of organisms and is not affected by antibiotics that suppress growth on culture plates, it can be used to advantage in following bacteriologic responses and relapses in patients receiving oral therapy [351,380]. The use of fluorescent antibody techniques offers many advantages in the surveillance and epidemiologic control of EPEC gastroenteritis. Immunofluorescent methods should supplement, but not replace, standard bacteriologic and serologic methods for identification of enteric pathogens.

Specific gene probes and PCR primers for the BFP adhesin, for the intimin-encoding gene (*eae*), and for a cryptic plasmid locus (EAF) are available [112]. Detection of BFP or EAF is superior to detection of *eae* because many non-EPEC, including nonpathogens, carry the *eae* gene [112,381]. PCR and gene probe analysis can be performed directly on the stools of suspect infants. Confirmation of infection by the identification of the organism in pure culture should be pursued.

Before widespread use of molecular methods, the HEp-2 cell adherence assay was proposed for EPEC diagnosis [135]. The presence of a focal or localized adherence [135] pattern on the surface of HEp-2 or HeLa cells after 3-hour coincubation is a highly sensitive and specific test for detection of EPEC [382]. The requirement for cell culture and expertise in reading this assay limits its utility to the research setting. An ELISA for BFP has been described, but is not readily available [383]. The capacity of localized adherence plus EPEC to polymerize F-actin can be detected in tissue culture cells stained with rhodamine-labeled phalloidin [384]. This fluorescence-actin staining test is cumbersome and impractical for routine clinical use.

## Prognosis

The mortality rate recorded previously in epidemics of EPEC gastroenteritis is impressive for its variability. During the 1930s and 1940s, when organisms later recognized as classic enteropathogenic serotypes were infecting infants, the case-fatality ratio among neonates was about 50% [227,351]. During the 1950s and 1960s, about one of every four infected infants still died in many nursery epidemics, but several outbreaks involving the same serotypes under similar epidemiologic circumstances had fatality rates of less than 3% [251,258,268]. In the 1970s, reports appeared in the literature of a nursery epidemic with a 40% neonatal mortality rate [301] and of an extensive outbreak in a nursery for premature infants with 4% fatalities [281]; another report stated that among "243 consecutive infants admitted to the hospital for EPEC diarrheal disease, none died of diarrheal disease per se." [385].

A significant proportion of the infants who died during or shortly after an episode of gastroenteritis already were compromised by preexisting disease [250,299,345] or by congenital malformations [231,248,257] at the time they acquired gastroenteritis. These underlying pathologic conditions seem to exert a strongly unfavorable influence, probably by reducing the infant's ability to respond to the added stresses imposed by the GI tract infection. Although prematurity is often mentioned as a factor predisposing to a fatal outcome, the overall mortality rate

among premature infants with EPEC gastroenteritis has not differed significantly over the years from the mortality recorded for term infants [250,278,280].

## Therapy

The management of EPEC gastroenteritis should be directed primarily toward prevention or correction of problems caused by loss of fluids and electrolytes [214]. Most neonates have a relatively mild illness that can be treated with oral rehydration. Infants who appear toxic, infants with voluminous diarrhea and persistent vomiting, and infants with increasing weight loss should be hospitalized for observation and treatment with parenteral fluids and careful maintenance of fluid and electrolyte balance and possibly with antimicrobial therapy. Clinical studies suggest that slow nasogastric infusion of an elemental diet can be valuable in treating infants who have intractable diarrhea that is unresponsive to standard modes of therapy [386].

There is no evidence that the use of proprietary formulas containing kaolin or pectin is effective in reducing the number of diarrheal stools in neonates with gastroenteritis. Attempts to suppress the growth of enteric pathogens by feeding lactobacillus to the infant in the form of yogurt, powder, or granules have not been shown to be valuable [387]. A trial of cholestyramine in 15 newborns with EPEC gastroenteritis had no effect on the duration or severity of diarrhea [281]. The use of atropine-like drugs, paregoric, or loperamide to reduce intestinal motility or cramping should be avoided. Inhibition of peristalsis interferes with an efficient protective mechanism designed to rid the body of intestinal pathogens and may lead to fluid retention in the lumen of the bowel that may be sufficient to mask depletion of extracellular fluid and electrolytes.

The value of antimicrobial therapy in management of neonatal EPEC gastroenteritis, if any, is uncertain. There are no adequately controlled studies defining the benefits of any antibiotic in eliminating EPEC from the GI tract, reducing the risk of cross-infection in community or nursery outbreaks, or modifying the severity of the illness. Proponents of the use of antimicrobial agents have based their claims for efficacy on anecdotal observations or comparative studies [262]. Nonetheless, several clinical investigations have provided sufficient information to guide the physician faced with the dilemma of deciding whether to treat an individual infant or an entire nursery population with EPEC diarrheal disease. These guidelines must be considered tentative, however, until rigidly controlled, double-blind studies have established the efficacy of antibiotics on a more rational and scientific basis.

Oral therapy with neomycin [251,268], colistin [380], or chloramphenicol [361] seems to be effective in rapidly reducing the number of susceptible EPEC organisms in the stool of infected infants. Studies comparing the responses of infants treated orally with neomycin [250], gentamicin [281], polymyxin [259], or kanamycin [388] with the responses of infants receiving supportive therapy alone have shown that complete eradication of EPEC occurs more rapidly in infants receiving an antimicrobial agent. Chloramphenicol is not recommended for use in neonates. In most cases, stool cultures are free of EPEC 2 to 4 days after the start of therapy [262,380]. Bacteriologic failure, defined as continued isolation of organisms during or after a course of an antimicrobial agent, can be expected to occur in 15% to 30% of patients [262, 281]. Such relapses generally are not associated with a recurrence of symptoms [248,251,262].

The effectiveness of oral antimicrobial therapy in reducing the duration of EPEC excretion serves to diminish environmental contamination and the spread of pathogenic organisms from one infant to another. Breaking the chain of fecal-oral transmission by administering antimicrobial agents simultaneously to all carriers of EPEC and their immediate contacts in the nursery has seemed to be valuable in terminating outbreaks that have failed to respond to more conservative measures [251,280,389]. The apparent reduction in morbidity and mortality associated with oral administration of neomycin [247,250, 251], colistin [263,283,301], polymyxin [259], or gentamicin [263] during nursery epidemics has led to the impression that these drugs also exert a beneficial clinical effect in severely or moderately ill infants. Reports describing clinical [272], bacteriologic [281], or histopathologic [334] evidence of tissue invasion by EPEC have persuaded some investigators to suggest the use of parenteral rather than oral drug therapy in debilitated or malnourished infants. On the basis of these data, there seems to be sufficient evidence to recommend oral administration of nonabsorbable antibiotics in the treatment of severely or moderately ill newborns with EPEC gastroenteritis. The drug most frequently used for initial therapy is neomycin sulfate in a dosage of 100 mg/kg/day administered orally every 8 hours in three divided doses [262]. In communities in which neomycin-resistant EPEC has been prevalent, treatment with colistin sulfate or polymyxin B in a dosage of 15 to 20 mg/kg/day orally and divided into three equal doses may be appropriate. It is rarely necessary to use this approach, however.

Treatment should be continued only until stool cultures become negative for EPEC [262]. Because of the unavoidable delay before cultures can be reported, most infants receive therapy for 3 to 5 days. If fluorescent antibody testing of rectal swab specimens is available, therapy can be discontinued as soon as EPEC no longer is identified in smears; this takes no more than 48 hours in more than 90% of cases [262]. After diarrhea and vomiting have stopped, and the infant tolerates formula feedings, shows a steady weight gain, and appears clinically well, discharge with outpatient follow-up is indicated. Bacteriologic relapses do not require therapy, unless they are associated with illness or high epidemiologic risks to other young infants in the household. Because the infecting organisms in these recurrences generally continue to show in vitro susceptibility to the original drug, it should be reinstituted pending bacteriologic results [262].

When clinical judgment suggests that a neonate may have bacterial sepsis and EPEC diarrheal disease, parenteral antimicrobial therapy is indicated after appropriate cultures have been obtained. The routine use of systemic therapy in severe cases of EPEC enteritis is inappropriate on the basis of current clinical experience.

Antimicrobial susceptibility patterns of EPEC are an important determinant of the success of therapy in infections with these organisms [250,263,264]. These patterns are unpredictable, depending on the ecologic pressures exerted by local antibiotic usage [263,264] and on the incidence of transmissible resistance factors in the enteric flora of the particular population served by an institution [390–395]. For these reasons, variations in susceptibility patterns are apparent in different nurseries [263,393] and even occasionally within the same institution [264,265,267]. Sudden changes in clinical response may occur during the course of a single epidemic as drug-susceptible strains of EPEC are replaced by strains with multidrug resistance [250,307,392]. Because differences can exist in the susceptibilities of different EPEC serogroups to various antimicrobial agents, regional susceptibility patterns should be reported on the basis of OB group or serotype rather than for EPEC as a whole [267]. Knowledge of the resistance pattern in one's area may help in the initial choice of antimicrobial therapy.

### Prevention

The prevention of hospital outbreaks of EPEC gastroenteritis is best accomplished by careful attention to infection control policies for a nursery. All infants hospitalized with diarrhea should have a bacteriologic evaluation. If the laboratory is equipped and staffed to perform fluorescent antibody testing, infants transferred from another institution to a newborn, premature, or intensive care nursery and all infants with gastroenteritis on admission during an outbreak of EPEC diarrhea or in a highly endemic area can be held in an observation area for 1 or 2 hours until the results of the fluorescent antibody test or PCR are received. Because of the difficulty in diagnosing EPEC infection, reference laboratories, such as those at the U.S. Centers for Disease Control and Prevention (CDC), should be notified when an outbreak is suspected. Infants suspected to be excreting EPEC, even if healthy in appearance, can be separated from other infants and given oral therapy until the test results are negative.

Some experts have suggested that when the rapid results obtainable with fluorescent antibody procedures are unavailable, all infants admitted with diarrhea in a setting where EPEC is common may be treated as if they were excreting EPEC or some other enteric pathogen until proven otherwise [389]. Stool cultures should be obtained at admission, and contact precautions should be enforced among all individuals who come into contact with the infant. Additional epidemiologic studies are needed to establish the advantages of careful isolation and nursing techniques, particularly in smaller community hospitals in which the number of infants in a "gastroenteritis ward" may be small. The use of prophylactic antibiotics has been shown to be of no value and can select for increased resistance [394–396].

It can be difficult to keep a nursery continuously free of EPEC. Specific procedures have been suggested for handling a suspected outbreak of bacterial enteritis in a newborn nursery or infant care unit [252,371,373]. Evidence indicating that a significant proportion of *E. coli* enteritis may be caused by nontypable strains has required some modification of these earlier recommendations. The following infection control measures may be appropriate:

1. The unit is closed, when possible, to all new admissions.
2. Personnel and parents should pay scrupulous attention to hand hygiene when handling infants.
3. Cultures for enteric pathogens are obtained from nursing personnel assigned to the unit at the time of the outbreak.
4. Stool specimens obtained from all infants in the nursery can be screened by the fluorescent antibody or another technique and cultured. Identification of a classic enteropathogenic serotype provides a useful epidemiologic marker; however, failure to isolate one of these strains does not eliminate the possibility of illness caused by nontypable EPEC.
5. Antimicrobial therapy with oral neomycin or colistin can be considered for all infants with a positive fluorescent antibody test or culture result. The initial drug of choice depends on local patterns of susceptibility. Depending on the results of susceptibility tests, subsequent therapy may require modification.
6. If an identifiable EPEC strain is isolated, second and third stool specimens from all infants in the unit are reexamined by the fluorescent antibody technique or culture at 48-hour intervals. If this is impractical, exposed infants should be carefully followed.
7. Early discharge for healthy, mature, uninfected infants is advocated.
8. An epidemiologic investigation should be performed to seek the factor or factors responsible for the outbreak. A surveillance system may be established for all individuals in contact with the nursery, including physicians and other health care personnel, housekeeping personnel, and postpartum mothers with evidence of enteric disease. A telephone, mail, or home survey may be conducted on all infants who were residing in the involved unit during the 2 weeks before the outbreak.
9. When all patients and contacts are discharged and control of the outbreak is achieved, a thorough terminal disinfection of the involved nursery is mandatory [397].

## Enterohemorrhagic *Escherichia coli*

Since a multistate outbreak of enterohemorrhagic colitis was associated with *E. coli* O157:H7 [398], Shiga toxin–producing *E. coli* (STEC) have been recognized as emerging GI pathogens in most of the industrialized world. A particularly virulent subset of STEC, EHEC, causes frequent and severe outbreaks of GI disease [112,399]; the most virulent EHEC organisms belong to serotype O157:H7. EHEC has a bovine reservoir and is transmitted by undercooked meat; unpasteurized milk; and contaminated vegetables such as lettuce, alfalfa sprouts, and radish sprouts (as occurred in over 9000 schoolchildren in Japan) [400,401]. It also spreads directly

from person to person [401,402]. The clinical syndrome comprises bloody, noninflammatory (sometimes voluminous) diarrhea that is distinct from febrile dysentery with fecal leukocytes seen in shigellosis or EIEC infections [112]. Most cases of EHEC infections have been recognized in outbreaks of bloody diarrhea or HUS in day care centers, schools, nursing homes, and communities [402–404]. Although EHEC infections often involve infants and young children, the frequency of this infection in neonates is unclear; animal studies suggest that receptors for the Shiga toxin may be developmentally regulated and that susceptibility to disease may be age related [405].

The capacity of EHEC to cause disease is related to the phage-encoded capacity of the organism to produce a Vero cell cytotoxin, subsequently shown to be one of the Shiga toxins (first identified in strains of *Shigella dysenteriae* serotype 1) [406–408]. Shiga toxin 1 is neutralized by antiserum against the Shiga toxin of *S. dysenteriae*, whereas Shiga toxin 2, although biologically similar, is not neutralized by anti–Shiga toxin [409,410]. Similar to Shiga toxin made by *S. dysenteriae*, both *E. coli* Shiga toxins act by inhibiting protein synthesis by cleaving an adenosine residue from position 4324 in the 28S ribosomal RNA (rRNA) to prevent elongation factor-1–dependent aminoacyl transfer RNA (tRNA) from binding to the 60S rRNA [406,407]. The virulence of EHEC may also be determined in part by a 60-MDa plasmid that encodes for a fimbrial adhesin in O157 and O26 [411,412]. This phenotype is mediated by the LEE pathogenicity island, which is highly homologous to the island present in EPEC strains [343].

EHEC and other STEC infections should be suspected in neonates who have bloody diarrhea or who may have been exposed in the course of an outbreak among older individuals. Because most cases are caused by ingestion of contaminated food, neonates have a degree of epidemiologic protection from the illness. STEC diarrhea is diagnosed by isolation and identification of the pathogen in the feces. *E. coli* O157:H7 does not ferment sorbitol, and this biochemical trait is commonly used in the detection of this serotype [112,413]. Because some nonpathogenic *E. coli* share this characteristic, confirmation of the serotype by slide agglutination is required. These techniques can be performed in most clinical laboratories. Detection of non-O157 serotypes is problematic, however, and relies on detection of the Shiga toxin; available methods include Shiga toxin ELISA, latex agglutination, and molecular methods [112,413].

Diarrhea-related HUS is almost always caused by STEC; some cases of HUS in infants are not associated with diarrhea or STEC. Even in older patients, the stool is typically negative for STEC at the time that HUS develops [414,415]. Serum and fecal detection of cytotoxin has been performed in such patients, but no diagnostic modality is definitive when HUS has supervened [414,415].

Antimicrobial therapy should not be administered to patients who may have STEC infection, although the role of antimicrobial therapy in inducing HUS is controversial [416,417]. Management of diarrhea and possible sequelae is supportive, with proper emphasis on fluid and electrolyte replacement. Aggressive rehydration is helpful in minimizing the frequency of serious sequelae. Antimotility agents are contraindicated because they may prolong the duration of STEC-associated bloody diarrhea [417a].

## Enteroaggregative *Escherichia coli*

The HEp-2 adherence assay is useful for the detection of EPEC organisms, which exhibit a classic localized adherence pattern [135]. Two other adherence patterns can be discerned in this assay: aggregative and diffuse. These two patterns have been suggested to define additional pathotypes of diarrheogenic *E. coli* [112]. Strains exhibiting the aggregative adherence pattern (i.e., EAEC) are common pathogens of infants [140].

EAEC cause diarrhea by colonization of the intestinal mucosa and elaboration of enterotoxins and cytotoxins [140,418]. Many strains can be shown to elicit secretion of inflammatory cytokines in vitro, which may contribute to growth retardation associated with prolonged but otherwise asymptomatic colonization [119]. Several virulence factors in EAEC are under the control of the virulence gene activator AggR [418]. The presence of the AggR regulator or its effector genes has been proposed as a means of detecting truly virulent EAEC strains (called typical EAEC) [418,419], and an empirical gene probe long used for EAEC detection has been shown to correspond to one gene under AggR control [420,421].

### *Epidemiology and Transmission*

The mode of transmission of EAEC has not been well established. In adult volunteer studies, the infectious dose is high (>$10^8$ colony-forming units), suggesting that in adults at least, person-to-person transmission is unlikely [422,423]. Several outbreaks have been linked to consumption of contaminated food [424,425]. The largest of these outbreaks involved almost 2700 schoolchildren in Japan [424]; a contaminated school lunch was the implicated source of the outbreak. Some studies have shown contamination of condiments or milk, which could represent vehicles of food-borne transmission.

Several nursery outbreaks of EAEC have been observed [426,427], although in no case has the mechanism of transmission been established. The first reported nursery outbreak involved 19 infants in Nis, Serbia, in 1995. Because these infants did not ingest milk from a common source, it is presumed that horizontal transmission by environmental contamination or hands of health care personnel was possible. Most of the infants were full term and previously well, and they were housed in two separate nursery rooms.

The earliest epidemiologic studies of EAEC implicated this organism as a cause of endemic diarrhea in developing countries [428–430]. In this setting, EAEC as defined by the aggregative adherence pattern of adherence to HEp-2 cells can be found in upward of 30% of the population at any one time [431]. Newer molecular diagnostic modalities have revised this figure downward, although the organism remains highly prevalent in many areas. Several studies from the Indian subcontinent implicated EAEC among the most frequent enteric pathogens [428,429,432]. Other sites reproducibly reporting high

incidence rates include Mexico [430] and Brazil [431,433]. There is evidence that EAEC may be increasing in incidence. A study from São Paulo, Brazil, implicated EAEC as the prevalent *E. coli* pathotypes in infants [433], replacing EPEC in this community. Many other sites in developing countries of Africa [434], Asia [419,435], and South America [436] have described high endemic rates.

Several studies have suggested that EAEC is also a common cause of infant diarrhea in industrialized countries [437–439]. Using molecular diagnostic methods, a large prospective study in the United Kingdom implicated EAEC as the second most common enteric bacterial pathogen after *Campylobacter* [440]. A similar survey from Switzerland found EAEC to be the most common bacterial enteropathogen [437]. Studies from the United States also have shown a high rate of EAEC diarrhea in infants; using molecular diagnostic methods, EAEC was implicated in 11% and 8% of outpatient and inpatient diarrhea cohorts compared with less than 2% of asymptomatic control infants ($P < .05$) [441]. Although epidemiologic studies have shown that EAEC can cause diarrhea in all age groups, several studies suggest that the infection is particularly common in infants younger than 12 months [419,436].

### *Clinical Manifestations*

Descriptions from outbreaks and volunteer studies suggest that EAEC diarrhea is watery in character with mucus, but without blood or frank pus [422,423,426]. Patients typically are afebrile. Several epidemiologic studies have suggested that many infants may have bloody diarrhea [430], but fecal leukocytes are uncommon.

The earliest reports of EAEC infection suggested that this pathogen may be particularly associated with persistent diarrhea (>14 days) [428–430]. Later studies suggest, however, that persistent diarrhea may occur in only a subset of infected infants [424]. In the Serbian outbreak of 19 infected infants, the mean duration of diarrhea was 5.2 days [426]; diarrhea persisted more than 14 days in only 3 patients. Infants in this outbreak had frequent, green, odorless stools. In three cases, the stools had mucus, but none had visible blood. Eleven infants developed temperatures greater than 38° C (>100.4° F); only one had vomiting.

Despite a lack of clinical evidence suggesting inflammatory enteritis, several clinical studies have suggested that EAEC is associated with subclinical inflammation, including the shedding of fecal cytokines and lactoferrin [119,442]. Studies in Fortaleza, Brazil, suggest that children asymptomatically excreting EAEC may exhibit growth shortfalls compared with uninfected peers [119]. A study from Germany reported an association between EAEC isolation and colic in infants without diarrhea [439]. This association was not observed again. EAEC should be considered in the differential diagnosis of persistent diarrhea and failure to thrive in infants.

### *Diagnosis and Therapy*

Diagnosis of EAEC requires identification of the organism in the patient's feces. The HEp-2 adherence assay can be used for this purpose [135]. Some reports suggest that the adherence phenotype can be observed using formalin-fixed cells [443,444], obviating the need to cultivate eukaryotic cells for each assay. PCR for typical EAEC is available and is the preferred diagnostic test [114,445].

Antibiotic therapy using fluoroquinolones in adult patients has been successful [446]. Preliminary studies suggest that azithromycin [447] or rifaximin [448] also may be effective. Therapy in infected infants should be guided by the results of susceptibility testing because EAEC organisms are frequently antibiotic resistant [434].

## Other *Escherichia coli* Pathotypes

Additional *E. coli* pathotypes have been described, including diffusely adherent *E. coli* (DAEC) [449], and cytodetaching *E. coli* [450]. DAEC has been specifically associated with diarrhea after infancy because infants may have some degree of inherent resistance to infection [451]. Cytodetaching *E. coli* represent organisms that secrete the *E. coli* hemolysin [452]. It is unclear whether these latter organisms are true enteric pathogens.

# *SALMONELLA*

## Nature of the Organism

Taxonomists classify virtually all pathogenic *Salmonella* strains as a single species, *Salmonella enterica*. Numerous distinct serovars exist within this species, although historically these have been designated as though they were species unto themselves. *Salmonella* strains are correctly designated *S. enterica* serovar Typhi (or simply *S. typhi*) or *S. enterica* serovar Enteritidis. Biochemical and serologic traits are used routinely by hospital laboratories to differentiate *Salmonella* serovars. *S. typhi* is different from other salmonellae because it does not produce gas from glucose [453]. Because there are several thousand serovars designated *S. enteritidis*, serotyping of *S. enteritidis* is usually performed by state health departments rather than by hospital laboratories. The most common serogroups and representative serotypes are listed in Table 11–3. Infection of humans with the other serogroups (e.g., $C_3$, $D_2$, $E_2$, $E_3$, F, G, H, I) is uncommon.

There are differences in invasiveness of *Salmonella* strains related to serotype. *S. typhi*, *S. choleraesuis*, *Salmonella heidelberg* [454,455], and *Salmonella dublin* [456] are particularly invasive, with bacteremia and extraintestinal focal infections occurring frequently. *Salmonella* species encode injected toxins closely related to the invasion plasmid antigens (Ipa) of *Shigella* species. These proteins mediate invasion of target epithelial cells in *Salmonella* and *Shigella* strains [457]. A common *Salmonella* virulence plasmid confers resistance to complement-mediated bacteriolysis by inhibition of insertion of the terminal C5b-9 membrane attack complex into the outer membrane [458,459]. Laboratory studies have shown dramatic strain-related difference in the ability of *Salmonella typhimurium* to evoke fluid secretion, to invade intestinal mucosa, and to disseminate beyond the gut [460]. The production of an enterotoxin that is immunologically related to cholera toxin by about two thirds of *Salmonella* strains may play a role in the watery diarrhea commonly seen [461]. The significance of protein synthesis–

**TABLE 11–3** Common Serotypes and Serogroups of *Salmonella*

| Serogroups | Serotypes |
|---|---|
| A | Paratyphi A |
| B | Agona |
| | Derby |
| | Heidelberg |

| $E_4$ | Krefeld |
| | Senftenberg |

inhibiting cytotoxins [462] remains to be proved, although such toxins can damage gut epithelium, which could facilitate invasion. The cytotoxins produced by *Salmonella* are not immunologically related to Shiga toxin made by *S. dysenteriae* type 1 [463] or *E. coli* O157:H7.

Salmonellae have the ability to penetrate epithelial cells and reach the submucosa, where they are ingested by phagocytes [464]. In phagocytes, salmonellae are resistant to killing, in part because of the properties of their lipopolysaccharides [465,466] and multiple enzymes for oxidant defense [466a]. Persistence of the organism within phagolysosomes of phagocytic cells may occur with any species of *Salmonella*. It is unclear how the organisms have adapted to survive in the harsh intracellular environment, but their survival has major clinical significance, accounting for relapse after antibiotic therapy and the inadequacy of some antimicrobial agents that do not penetrate phagolysosomes. It is also perhaps the reason for prolonged febrile courses that occur even in the face of appropriate therapy. Although humoral immunity and cell-mediated immunity are stimulated during *Salmonella* infections, it is believed that cell-mediated immunity plays a greater role in eradication of the bacteria [467]. T-cell activation of macrophages seems to be important in killing intracellular *Salmonella* [468]. Defective interferon-γ production by monocytes of newborns in response to *S. typhimurium* lipopolysaccharide may explain in part the unusual susceptibility of infants to *Salmonella* infection [469]. Studies in mice suggest that T helper type 1 cell responses in Peyer patches and mesenteric lymph nodes may be central to protection of the intestinal mucosa [470]. Humans who lack the interleukin-12 receptor and have impaired T helper type 1 cell responses and interferon-γ production are at increased risk for *Salmonella* infection [471].

*S. typhi* strains comprise almost entirely a single global clone, recognized by serologic and biochemically distinct characteristics. *S. typhi* does not carry the virulence plasmid of nontyphoid *Salmonella*, but many of the other virulence properties are shared. *S. typhi* alone expressed the Vi antigen, a surface capsule that inhibits phagocytosis. Patients who develop classic enteric fever have positive stool cultures in the first few days after ingestion of the organism and again late in the course after a period of bacteremia. This course reflects early colonization of the gut, penetration of gut epithelium with infection of mesenteric lymph nodes, and reseeding of the gut during a subsequent bacteremic phase [472]. Studies of *S. typhimurium* in monkeys suggest similar initial steps in pathogenesis (e.g., colonization of gut, penetration of gut epithelium, infection of mesenteric lymph nodes), but failure of the organism to cause a detectable level of bacteremia [473].

Although *Salmonella* and *Shigella* invade intestinal mucosa, the resultant pathologic changes are different. *Shigella* multiply within and kill enterocytes with production of ulcerations and a brisk inflammatory response, whereas *Salmonella* pass through the mucosa and multiply within the lamina propria, where the organisms are ingested by phagocytes; consequently, ulcer formation is less striking [460], although villus tip cells are sometimes sloughed. Acute crypt abscesses can be seen in the stomach and small intestine, but the most dramatic changes occur in the colon, where acute diffuse inflammation with mucosal edema and crypt abscesses are the most consistent findings [474,475]. With *S. typhi*, there also is hyperplasia of Peyer patches in the ileum, with ulceration of overlying tissues.

## Epidemiology and Transmission

*Salmonella* strains, with the exception of *S. typhi*, are carried by various vertebrate animal hosts; human infection often can be traced to infected meat, contaminated milk, or contact with a specific animal. Half of commercial poultry samples are contaminated with *Salmonella* [476]. Definition of the serotype causing infection can sometimes suggest the likely source. *S. dublin* is closely associated with cattle; human cases occur with a higher-than-predicted frequency in people who drink raw milk [456]. For *S. typhimurium*, which is the most common serotype and accounts for more than one third of all reported human cases, a single source has not been established, although there is an association with cattle. Despite the 1975 ban by the U.S. Food and Drug Administration (FDA) on interstate commercial distribution of

small turtles, these animals continue to be associated with infection, as illustrated by a series of cases in Puerto Rico [477]. Various pet reptiles are an important source of various unusual *Salmonella* serotypes such as *Salmonella marina*, *Salmonella chameleon*, *Salmonella arizonae*, *Salmonella java*, *Salmonella stanley*, *Salmonella poona*, *Salmonella jangwain*, *Salmonella tilene*, and several others [478–480]. Salmonella organisms are hardy and capable of prolonged survival; organisms have been documented to survive in flour for nearly a year [481]. *Salmonella tennessee* has been shown to remain viable for many hours on non-nutritive surfaces (i.e., glass, 48 hours; stainless steel, 68 hours; enameled surface, 114 hours; rubber mattress, 119 hours; linen, 192 hours; and rubber tabletop, 192 hours) [482].

Infection with *Salmonella* is, similar to most enteric infections, more common in young children than in adults. The frequency of infection is far greater in the first 4 years of life; roughly equal numbers of cases are reported during each decade beyond 4 years of age. Although the peak incidence occurs in the 2nd through 6th months of life, infection in neonates is relatively common. Researchers at the CDC have estimated the incidence of *Salmonella* infection in the first month of life at nearly 75 cases per 100,000 infants [483].

Adult volunteer studies suggest that large numbers of *Salmonella* ($10^5$ to $10^9$) need to be ingested to cause disease [484]. It is likely, however, that lower doses cause illness in infants. The occurrence of nursery outbreaks [482,485–510] and intrafamilial spread [511] suggests that organisms are easily spread from person to person; this pattern is typical of low-inoculum diseases transmitted by the fecal-oral route. A neonate with *Salmonella* infection infrequently acquires the organism from his or her mother during delivery. Although the index case in an outbreak can often be traced to a mother [488–491,509], subsequent cases result from contaminated objects in the nursery environment [512,513] serving as a reservoir coming in contact with hands of attending personnel [482,497]. The mother of an index case may be symptomatic [493,494,514,515] or asymptomatic with preclinical infection [498], convalescent infection [491,495,516], or chronic carriage [517]. The risk of a newborn becoming infected when *Salmonella* is introduced into a nursery has been reported to be 20% to 27% [501,507], but the frequency of infection may be lower because isolated cases outside the context of a subsequent epidemic are unlikely to be reported.

Gastric acidity is an important barrier to *Salmonella* infection. Patients with anatomic or functional achlorhydria are at increased risk of developing salmonellosis [518,519]. The hypochlorhydria [37] and rapid gastric emptying typical of early life [40] may partly explain the susceptibility of infants to *Salmonella*. Premature and low birth weight infants seem to be at higher risk of acquiring *Salmonella* infection than term neonates [497,499]. Whether this higher risk reflects increased exposure because of prolonged hospital stays or increased susceptibility on the basis of immature intestinal or immune function is unclear.

Contaminated food or water is often the source of *Salmonella* infection in older patients; the limited diet of the infant makes contaminated food a less likely source of infection. Although human milk [520–522], raw milk [523], powdered milk [524–526], formula [507], and cereal [527] have been implicated in transmission to infants, more often fomites, such as delivery room resuscitators [485], rectal thermometers [500,528], oropharyngeal suction devices [529–531], water baths for heating formula [531], soap dispensers [532], scales [482,486,533], "clean" medicine tables [482], air-conditioning filters [482], mattresses, radiant warmers [512], and dust, serve as reservoirs. One unusual outbreak involving 394 premature and 122 term infants was traced to faulty plumbing, which caused massive contamination of environment and personnel [507]. After *Salmonella* enters a nursery, it is difficult to eradicate. Epidemics lasting 6 to 7 weeks [500,505], 17 weeks [482], 6 months [499,504], 1 year [494], and 27 to 30 months [501,507] have been reported. Spread to nearby pediatric wards has occurred [502,508].

The incubation period in nursery outbreaks has varied widely in several studies where careful attention has been paid to this variable. In one outbreak of *Salmonella oranienburg* involving 35 newborns, 97% of cases occurred within 4 days of birth [501]. In an outbreak of *S. typhimurium*, each of the ill infants presented within 6 days of birth [491]. These incubation periods are similar to those reported for *Salmonella newport* in older children and adults, 95% of whom have been reported to be ill within 8 days of exposure [534,535]. Conversely, one outbreak of *Salmonella nienstedten* involving newborns was characterized by incubation periods of 7 to 18 days [502].

The usual incubation period associated with fecal-oral nursery transmission is not found with congenital typhoid. During pregnancy, typhoid fever is associated with bacteremic infection of the fetus. Congenitally infected infants are symptomatic at birth. They are usually born during the 2nd to 4th week of untreated maternal illness [536]. Usually, the mother is a carrier; fecal-oral transmission of *S. typhi* can occur with delayed illness in the newborn [537].

## Clinical Manifestations

Several major clinical syndromes occur with nontyphoidal *Salmonella* infection in young infants. Colonization without illness may be the most common outcome of ingestion of *Salmonella* by the neonate. Colonization usually is detected when an outbreak is under investigation. Most infected infants who become ill have abrupt onset of loose, green, mucus-containing stools, or they have bloody diarrhea; an elevated temperature is also a common finding in *Salmonella* gastroenteritis in the first months of life [455]. Grossly bloody stools are found in a few patients, although grossly bloody stools can occur in the first 24 hours of life. Hematochezia is more typically associated with noninfectious causes (e.g., swallowed maternal blood, intestinal ischemia, hemorrhagic diseases, anorectal fissures) at this early age [538].

There seem to be major differences in presentation related to the serotype of *S. enteritidis* causing infection. In one epidemic of *S. oranienburg* [501] involving 46 newborns, 76% had grossly bloody stools, 11% were febrile, 26% had mucus in their stools, and only 11% were healthy. In a series of *S. newport* infections involving

11 premature infants [488], 90% of infants with gastroenteritis had blood in their stools, 10% had fever, 10% had mucus in their stools, and 9% were asymptomatic. In an outbreak of *S. typhimurium* [491] involving 11 ill and 5 healthy infants, none had bloody stools; all of the symptomatic infants were febrile and usually had loose green stools. Of 26 infants infected by *Salmonella virchow*, 42% were asymptomatic; the rest had mild diarrhea [496]. Seals and colleagues [502] described 12 infants with *S. nienstedten*, all of whom had watery diarrhea and low-grade fever; none had bloody stools. In a large outbreak in Zimbabwe of *S. heidelberg* infection reported by Bannerman [499], 38% of 100 infants were asymptomatic, 42% had diarrhea, 16% had fever, 15% had pneumonia, and 2% developed meningitis. An outbreak of *Salmonella worthington* was characterized primarily by diarrhea, fever, and jaundice, although 3 of 18 infants developed meningitis, and 17% died [529]. In dramatic contrast to these series, none of 27 infants with positive stool cultures for *S. tennessee* had an illness in a nursery found to be contaminated with that organism [483]. A few infants with *Salmonella* gastroenteritis have developed necrotizing enterocolitis [506,539], but it is unclear whether *Salmonella* was the cause.

Although gastroenteritis is usually self-limited, chronic diarrhea has sometimes been attributed to *Salmonella* [517,540]. Whether chronic diarrhea is caused by Salmonella is uncertain. Although some infants develop carbohydrate intolerance after a bout of *Salmonella* enteritis [541,542], and *Salmonella* is typically listed as one of the causes of postinfectious protracted diarrhea [543], it is difficult to be sure that the relationship is causal. The prolonged excretion of *Salmonella* after a bout of gastroenteritis may sometimes cause nonspecific chronic diarrhea to be erroneously attributed to *Salmonella*.

Major extraintestinal complications of *Salmonella* infection may develop in a neonate who becomes bacteremic. Systemic spread may develop in infants who initially present with diarrhea and in some who have no GI tract signs. Bacteremia seems to be more common in neonates than in older children [544]. A study of more than 800 children with *Salmonella* infection showed that extraintestinal infection occurred significantly more often (8.7% versus 3.6%) in the first 3 months of life [545]. Several retrospective studies suggest that infants in the first month of life may have a risk of bacteremia of 30% to 50% [455]. One retrospective study [454] suggested that the risk is not increased in infancy and estimated that the risk of bacteremia in childhood *Salmonella* gastroenteritis is 8.5% to 15.6%. Prospective studies of infants in the first year of life suggest that the risk of bacteremia is 1.8% to 6% [546,547]. Although selection biases in these studies limit the reliability of these estimates, the risk is substantial.

*Salmonella* species isolated from infants include some serotypes that seem to be more invasive in the first 2 months of life than in older children or healthy adults (*S. newport*, *Salmonella agona*, *Salmonella blockley*, *Salmonella derby*, *S. enteritidis*, *S. heidelberg*, *Salmonella infantis*, *Salmonella javiana*, *Salmonella saint-paul*, and *S. typhimurium*) and serotypes that are aggressive in every age group (*S. choleraesuis* and *S. dublin*). Other serotypes seem more likely to cause bacteremia in adults (*S. typhi*, *Salmonella paratyphi A*, and *Salmonella paratyphi B*) [544].

Virtually any *Salmonella* serotype can cause bacteremic disease in neonates. A few infants with *Salmonella* gastroenteritis have died with *E. coli* or *Pseudomonas aeruginosa* sepsis [508], and the role of *Salmonella* in these cases is unclear. In contrast to the situation in older children, in whom bacteremic salmonellosis often is associated with underlying medical conditions, bacteremia may occur in infants who have no immunocompromising conditions [548]. *Salmonella* bacteremia is often not suspected clinically because the syndrome is not usually distinctive [454,455]. Even afebrile, well-appearing children with *Salmonella* gastroenteritis have been documented to have bacteremia that persists for several days [549].

Although infants with bacteremia may have spontaneous resolution without therapy [550], a sufficient number develop complications to warrant empirical antimicrobial therapy when bacteremia is suspected. The frequency of complications is highest in the 1st month of life. Meningitis is the most feared complication of bacteremic *Salmonella* disease. Of all cases of nontyphoidal *Salmonella* meningitis, 50% to 75% occur in the first 4 months of life [551]. The serotypes associated with neonatal meningitis (*S. typhimurium*, *S. heidelberg*, *S. enteritidis*, *S. saint-paul*, *S. newport*, and *Salmonella panama*) [511] are serotypes frequently associated with bacteremia. Meningitis has a high mortality rate, in part because of high relapse rates. Relapse has been reported in 64% of cases [552]. In some studies, more than 90% of patients with meningitis have died [553], although more typically, 30% to 60% of infants die [554,555]. The survivors experience the expected complications of gram-negative neonatal meningitis, including hydrocephalus, seizures, ventriculitis, abscess formation, subdural empyema, and permanent neurologic impairment. Neurologic sequelae have included retardation, hemiparesis, epilepsy, visual impairment, and athetosis [551].

In large nursery outbreaks, it is common to find infants whose course is complicated by pneumonia [499], osteomyelitis [556,557], or septic arthritis [497,499]. Other rare complications of salmonellosis include pericarditis [558], pyelitis [559], peritonitis [491], otitis media [491], mastitis [560], cholecystitis [561], endophthalmitis [562], cutaneous abscesses [506], and infected cephalhematoma [556]. Certain focal infections seen in older children and adults, such as endocarditis and infected aortic aneurysms, rarely or never have been reported in neonates [551,563]. Although the mortality rate in two reviews of nursery outbreaks was 3.7% to 7% [509,510], in some series, the mortality was 18% [499].

Enteric fever, most often related to *S. typhi*, but also occurring with *S. paratyphi A*, *S. paratyphi B*, *Salmonella paratyphi C*, and other *Salmonella* species, is reported much less commonly in infants than in older patients. Infected infants develop typical findings of neonatal sepsis and meningitis. Current data suggest that mortality is about 30% [564]. In utero infection with *S. typhi* has been described. Typhoid fever [532,565] and nontyphoidal *Salmonella* infections [566] during pregnancy put women at risk of aborting the fetus. Premature labor usually occurs during the 2nd to 4th week of maternal typhoid if the woman is untreated [536]. In a survey of typhoid

fever in pregnancy during the preantibiotic era, 24 of 60 women with well-documented cases delivered prematurely, with resultant fetal death; the rest delivered at term, although only 17 infants survived [567]. The outlook for carrying the pregnancy to term and delivering a healthy infant seems to have improved dramatically during the antibiotic era. One of seven women with typhoid in a series still delivered a dead fetus with extensive liver necrosis, however [568]. In the preantibiotic era, about 14% of pregnant women with typhoid fever died [569]. With appropriate antimicrobial therapy, pregnancy does not seem to put the woman at increased risk of death. Despite these well-described cases, typhoid fever is rare early in life.

Of 1500 cases of typhoid fever that Osler and McCrae [570] reported, only 2 were in the 1st year of life. In areas where typhoid fever is still endemic, systematic search for infants with enteric fever has failed to find many cases. The few infections with *S. typhi* documented in children in the 1st year of life often manifest as a brief nondescript "viral syndrome" or as pneumonitis [571,572]. Fever, diarrhea, cough, vomiting, rash, and splenomegaly may occur. The fever may be high, and the duration of illness may be many weeks [536].

## Diagnosis

The current practice of early discharge of newborns, although potentially decreasing the risk of exposure, can make recognition of a nursery outbreak difficult. Diagnosis of neonatal salmonellosis should trigger an investigation for other cases. Other than diarrhea, signs of neonatal *Salmonella* infection are similar to the nonspecific findings seen in most neonatal infections. Lethargy, poor feeding, pallor, jaundice, apnea, respiratory distress, weight loss, and fever are common. Enlarged liver and spleen are common in neonates with positive blood cultures. Laboratory studies are required to establish the diagnosis because the clinical picture is not distinct. The fecal leukocyte examination reveals polymorphonuclear leukocytes in 36% to 82% [376,573] of persons with *Salmonella* infection, but it has not been evaluated in neonates. The presence of fecal leukocytes is consistent with colitis of any cause and is a nonspecific finding. Routine stool cultures usually detect *Salmonella* if two or three different enteric media (i.e., MacConkey, eosin–methylene blue, *Salmonella-Shigella*, Tergitol 7, xylose-lysine-deoxycholate, brilliant green, or bismuth sulfite agar) are used. Stool, rather than rectal swab material, is preferable for culture, particularly if the aim of culture is to detect carriers [574]. On the infrequent occasions when proctoscopy is performed, mucosal edema, hyperemia, friability, and hemorrhages may be seen [475].

Infants who are bacteremic often do not appear sufficiently toxic to raise the suspicion of bacteremia [575]. Blood cultures should be obtained as a routine part of evaluation of neonates with suspected or documented *Salmonella* infection. Ill neonates with *Salmonella* infection should have a cerebrospinal fluid examination performed. Bone marrow cultures also may be indicated when enteric fever is suspected. There are no consistent abnormalities in the white blood cell count. Serologic studies are not helpful in establishing the diagnosis, although antibodies to somatic [576,577] and flagellar antigens [501] develop in many infected newborns.

If an outbreak of salmonellosis is suspected, further characterization of the organism is imperative [478]. Determination of somatic and flagellar antigens to characterize the specific serotype may be crucial to investigate an outbreak. When the serotype found during investigation of an outbreak is a common one (e.g., *S. typhimurium*), antimicrobial resistance testing [489,578] and use of molecular techniques such as plasmid characterization [578] can be helpful in determining whether a single-strain, common-source outbreak is in progress.

## Therapy

As in all enteric infections, attention to fluid and electrolyte abnormalities is the first issue that must be addressed by the physician. Specific measures to eradicate *Salmonella* intestinal infection have met with little success. Multiple studies show that antibiotic treatment of *Salmonella* gastroenteritis prolongs the excretion of *Salmonella* [579–586]. Almost half of infected children in the first 5 years of life continue to excrete *Salmonella* 12 weeks after the onset of infection; more than 5% have positive cultures at 1 year [587]. No benefit of therapy has been shown in comparisons of ampicillin or neomycin versus placebo [583], chloramphenicol versus no antibiotic treatment [582], neomycin versus placebo [584], ampicillin or trimethoprim-sulfamethoxazole versus no antibiotic [581], and ampicillin or amoxicillin versus placebo [585]. In contrast to these studies, data suggest that there may be a role for quinolone antibiotics in adults and children [586,588], but these drugs are not approved for use in neonates, and resistance has been encountered [589].

Because these studies have few data regarding the risk-benefit ratio of therapy in the neonate, it is uncertain whether they should influence treatment decisions in neonates. Studies that have included a few neonates suggest little benefit from antimicrobial therapy [491,501,581, 590,591]. Because bacteremia is common in neonates, antimicrobial therapy for infants younger than 3 months who have *Salmonella* gastroenteritis often is recommended [546,547,575], however, especially if the infant appears toxic. Premature infants and infants who have other significant debilitating conditions also should probably be treated. The duration of therapy is debatable, but should probably be no more than 3 to 5 days if the infant is not seriously ill and if blood cultures are sterile. If toxicity, clinical deterioration, or documented bacteremia complicates gastroenteritis, prolonged treatment is indicated. Even with antimicrobial therapy, some infants develop complications. The relatively low risk of extraintestinal dissemination must be balanced against the well-documented risk of prolonging the carrier state. For infants who develop chronic diarrhea and malnutrition, hyperalimentation may be required; the role of antimicrobial agents in this setting is unclear. An infant with typhoid fever should be treated with an appropriate antimicrobial agent; relapses sometimes occur after therapy.

Colonized healthy infants discovered by stool cultures to harbor *Salmonella* during evaluation of an outbreak

ought to be isolated, but probably should not receive antimicrobial therapy. These infants should be discharged from the nursery as early as possible and followed carefully as outpatients.

Antimicrobial treatment of neonates who have documented extraintestinal dissemination must be prolonged. *Salmonella* bacteremia without localization is generally treated with at least a 10-day course of therapy. Therapy for meningitis must be given for at least 4 weeks to lessen the risk of relapse. About three fourths of patients who have relapses have been treated for 3 weeks or less [551]. Similar to meningitis, treatment for osteomyelitis must be prolonged to be adequate. Although cures have been reported with 3 weeks of therapy, 4 to 6 weeks of therapy is recommended.

In vitro susceptibility data for *Salmonella* isolates must be interpreted with caution. Aminoglycosides show good in vitro activity but poor clinical efficacy, perhaps because of the low pH of the phagolysosome; aminoglycosides have poor activity in an acid environment. The relative instabilities of some antibiotics in this acid environment also may explain in vitro and in vivo disparities. The intracellular localization and survival of *Salmonella* within phagocytic cells also presumably explains the relapses encountered with virtually every regimen. Resistance to antibiotics has long been a problem with *Salmonella* infection [579,592,593] and has been steadily increasing in the United States [594]. With the emergence of Typhimurium type DT 104, resistance to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline has increased from 0.6% in 1979 and 1980 to 34% in 1996 [595].

Resistance plasmids have been selected and transmitted partly because therapy has been given for mild illness that should not have been treated [579] and partly because of use of antibiotics in animal feeds. Resistance to chloramphenicol and ampicillin has made trimethoprim-sulfamethoxazole increasingly important for the treatment of *Salmonella* infection in patients who require therapy. With increasing resistance to all three of these agents in Asia [596], the Middle East [597], Africa [598], Europe [599, 600], Argentina [593], and North America [592,601,602], the third-generation cephalosporins and quinolones represent drugs of choice for invasive salmonellosis. The quinolones currently are not approved for patients younger than 18 years. Cefotaxime, ceftriaxone, and cefoperazone represent acceptable alternative drugs for typhoidal and nontyphoidal salmonellosis when resistance is encountered [603,604]. Because second-generation cephalosporins, such as cefuroxime, are less active in vitro than third-generation cephalosporins and are not consistently clinically effective, they should not be used [603,605]. Data suggest that cefoperazone may sterilize blood and cause patients with typhoid fever to become afebrile more rapidly than with chloramphenicol [606], perhaps because cefoperazone is excreted into bile in high concentrations [607]. Third-generation cephalosporins may have higher cure and lower relapse rates than ampicillin or chloramphenicol in children with *Salmonella* meningitis [608].

The doses of ampicillin, chloramphenicol, or cefotaxime used in infants with gastroenteritis pending results of blood cultures are the same as the doses used in treatment of sepsis. Because of the risk of gray baby syndrome, chloramphenicol should not be used in neonates unless other effective agents are unavailable. Trimethoprim-sulfamethoxazole, although useful in older children and adults, is not used in neonates because of the risk of kernicterus. Nosocomial infection with strains of *Salmonella* resistant to multiple antibiotics, including third-generation cephalosporins, has emerged as a problem in South America [593].

Nonantibiotic interventions may be important in the control of *Salmonella* infections. Limited data suggest that intravenous immunoglobulin (500 mg/kg on days 1, 2, 3, and 8 of therapy) coupled with antibiotic therapy may decrease the risk of bacteremia and death in preterm infants with *Salmonella* gastroenteritis [609].

## Prevention

Early recognition and intervention in nursery outbreaks of *Salmonella* are crucial to control. When a neonate develops salmonellosis, a search for other infants who have been in the same nursery should be undertaken. When two or more cases are recognized, environmental cultures, cultures of all infants, cohorting and contact isolation of infected infants, rigorous enforcement of hand hygiene, early discharge of infected infants, and thorough cleaning of all possible fomites in the nursery and delivery rooms are important elements of control. If cases continue to occur, the nursery should be closed to further admissions. Cultures of nursery personnel are likely to be helpful in the unusual situation of an *S. typhi* outbreak in which a chronic carrier may be among the caretakers. Whether culture of health care personnel during outbreaks of salmonellosis caused by other *Salmonella* species is helpful is debatable, although it is often recommended. Data suggest that nurses infected with *Salmonella* rarely infect patients in the hospital setting [610]. The fact that nursing personnel are sometimes found to be colonized during nursery outbreaks [482,488,501,503,504] may be a result rather than a cause of the epidemics.

The potential role of vaccines in control of neonatal disease is minimal. For most non–*S. typhi* serotypes, there is no prospect for an immunization strategy. Multiple doses of the commercially available oral live attenuated vaccine (Ty21a; Vivotif, Berna) have been shown in Chilean schoolchildren to reduce typhoid fever cases by more than 70% [611,612]. The vaccine is not recommended, however, for children younger than 6 years, partly because immunogenicity of Ty21a is age dependent; children younger than 24 months fail to respond with development of immunity [613]. Vi capsular polysaccharide vaccine is available for children older than 2 years and is effective in a single dose. Whether some degree of protection of infants could occur if stool carriage were reduced or could be transferred to infants by the milk of vaccinated mothers remains to be studied. Data suggest that breast-feeding may decrease the risk of other *Salmonella* infections [614].

# *SHIGELLA*

## Nature of the Organism

On the basis of DNA relatedness, shigellae and *E. coli* organisms belong to the same species [615]. For historical reasons and because of their medical significance,

**TABLE 11–4** *Shigella* Serogroups

| Serogroups | Species | No. Serotypes |
|---|---|---|
| A | *S. dysenteriae* | 13 |
| B | *S. flexneri* | 15 (including subtypes) |
| C | *S. boydii* | 18 |
| D | *S. sonnei* | 1 |

shigellae have been maintained as separate species, however. Shigellae are gram-negative bacilli that differ from typical *E. coli* because they do not metabolize lactose or do so slowly, are nonmotile, and generally produce no gas during carbohydrate use.

Shigellae are classically divided into four species (serogroups) on the basis of metabolic and antigenic characteristics (Table 11–4). The mannitol nonfermenters usually are classified as *S. dysenteriae*. Although the lipopolysaccharide antigens of the 13 recognized members of this group are not related to each other antigenically, these serotypes are grouped together as serogroup A. Serogroup D (*Shigella sonnei*) are ornithine decarboxylase–positive and slow lactose fermenters. All *S. sonnei* share the same lipopolysaccharide (O antigen). Shigellae that ferment mannitol (in contrast to *S. dysenteriae*), but do not decarboxylate ornithine or ferment lactose (*S. sonnei*) belong to serogroups B and C. Of these, the strains that have lipopolysaccharide antigens immunologically related to each other are grouped together as serogroup B (*Shigella flexneri*), whereas strains whose O antigens are not related to each other or to other shigellae are included in serogroup C (*Shigella boydii*). There are six major serotypes of *S. flexneri* and 13 subserotypes (1a, 1b, 2a, 2b, 3a, 3b, 4a, 4b, 5a, 5b, 6, X, and Y variant). There are 19 antigenically distinct serotypes of *S. boydii*. For *S. dysenteriae* and *S. boydii* serogroup confirmation, pools of polyvalent antisera are used.

The virulence of shigellae has been studied extensively since their recognition as major pathogens at the beginning of the 20th century [616,617]. The major determinants of virulence are encoded by a 120- to 140-MDa plasmid [618,619]. This plasmid, which is found in all virulent shigellae, encodes the synthesis of proteins that are required for invasion of mammalian cells and for the vigorous inflammatory response that is characteristic of the disease [620,621]. Shigellae that have lost this plasmid, have deletions of genetic material from the region involved in synthesis of these proteins, or have the plasmid inserted into the chromosome lose the ability to invade eukaryotic cells and become avirulent [622]; maintenance of the plasmid can be detected in the clinical microbiology laboratory by ability to bind Congo red. The ability to invade cells is the basic pathogenic property shared by all shigellae [623,624] and by *Shigella*-like invasive *E. coli*, which also possesses the *Shigella* virulence plasmid [223,620,621,625,626]. In the laboratory, *Shigella* invasiveness is studied in tissue culture (HeLa cell invasion), in animal intestine, or in rabbit or guinea pig eye, where instillation of the organism causes keratoconjunctivitis (Sereny test) [143]. Animal model studies have shown that bacteria penetrate and kill colonic mucosal cells and then elicit a brisk inflammatory response.

*Shigella* invasiveness is mediated by a set of toxins injected into host cells by virtue of a type III secretion system, which injects the proteins directly from the bacterial cytoplasm to the host cell cytoplasm. Shigella follows an unusual pathogenetic course. The bacteria invade the epithelial cell via pathogen-directed endocytosis. The bacteria then force lysis of the endocytic vacuole, gaining entry into the host cell cytoplasm. Here, the bacteria nucleate actin proteins into a structure with the appearance of a comet's tail behind the bacterium and use the force of this event to propel them into adjacent cells. This sequence promotes lateral spread through the mucosa. Some organisms pass through the epithelial barrier and are engulfed by macrophages, with subsequent release of proinflammatory cytokines. The release of these cytokines, coupled with the destruction of invaded epithelial cells, gives rise to the inflammatory, destructive nature of shigellosis.

Most key *Shigella* virulence factors are encoded on the virulence plasmid, but several chromosomal loci also enhance virulence [627,628]. This phenomenon has been best studied in *S. flexneri*, in which multiple virulence-enhancing regions of the chromosome have been defined [619,627–629]. The specific gene products of some of the chromosomal loci are unknown; one chromosomal virulence segment encodes for synthesis of the O repeat units of lipopolysaccharide. Intact lipopolysaccharide is necessary but not sufficient to cause virulence [627,630]. At least two cell-damaging cytotoxins that also are chromosomally encoded are produced by shigellae. One of these toxins (Shiga toxin) is made in large quantities by *S. dysenteriae* serotype 1 (the Shiga bacillus) and is made infrequently by other shigellae [631]. Shiga toxin is a major virulence factor in *S. dysenteriae*, enhancing virulence at the colonic mucosa and giving rise to sequelae similar to those caused by STEC (discussed earlier). This toxin kills cells by interfering with peptide elongation during protein synthesis [632–634]. Additional toxins may also be secreted by shigellae, although their roles in virulence are not established [635].

## Epidemiology

Although much of the epidemiology of shigellosis is predictable based on its infectious dose, certain elements are unexplained. Shigellae, similar to other organisms transmitted by the fecal-oral route, are commonly spread by food and water, but the low infecting inoculum allows person-to-person spread. Because of this low inoculum, *Shigella* is one of the few enteric pathogens that can infect swimmers [636]. The dose required to cause illness in adult volunteers is 10 organisms for *S. dysenteriae* serotype 1 [637], about 200 organisms for *S. flexneri* [638], and 500 organisms for *S. sonnei* [639]. Person-to-person transmission of infection probably explains the continuing occurrence of *Shigella* in the developed world. Enteropathogens that require large inocula and are best spread by food or drinking water are less common in industrialized societies because of sewage disposal facilities, water treatment, and food-handling practices. In the United States, day care centers currently serve as a major focus for acquisition of shigellosis [640]. Numerous outbreaks of shigellosis related to crowding, poor

sanitation, and the low dose required for diseases have occurred in this setting.

Given the ease of transmission, it is not surprising that the peak incidence of disease is in the first 4 years of life. It is, however, paradoxical that symptomatic infection is uncommon in the first year of life [641–644]. The best data on the age-related incidence of shigellosis come from Mata's [641] prospective studies of Guatemalan infants. In these studies, stool cultures were performed weekly on a group of children followed from birth to 3 years old. The rate of infection was more than 60-fold lower in the first 6 months of life than between 2 and 3 years (Fig. 11–1) [641]. The same age-related incidence has been described in the United States [644] and in a rural Egyptian village [643]. This anomaly has been explained by the salutary effects of breast-feeding [645–647]. It is likely, however, that breast-feeding alone does not explain the resistance of infants to shigellosis.

A review of three large case series [648–650] suggests that about 1.6% (35 of 2225) of shigellosis cases occur in infants in the neonatal period. The largest series of neonatal shigellosis [647] suggests that the course, complications, and etiologic serogroups are different in neonates than in older children. Although newborns are routinely contaminated by maternal feces, neonatal shigellosis is rare.

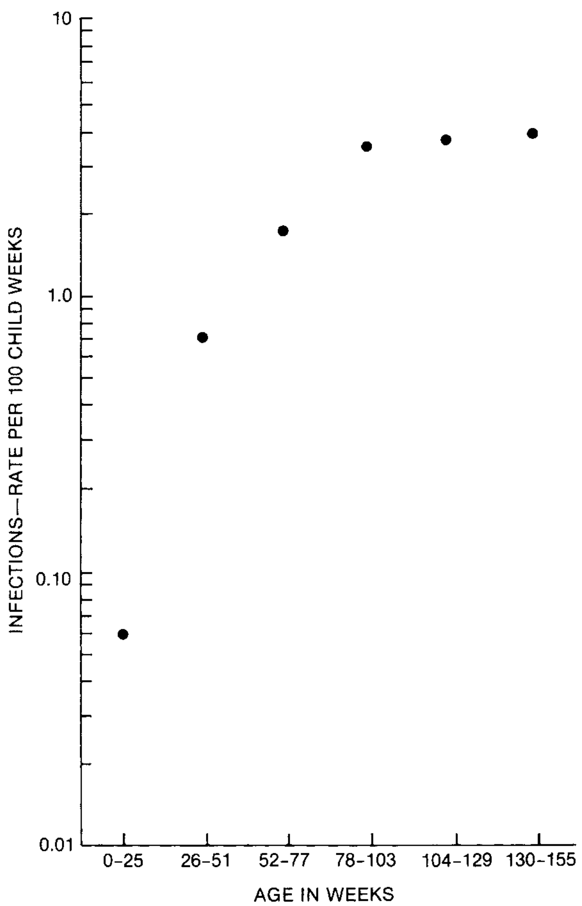

**FIGURE 11–1** Age-related incidence of *Shigella* infection. *(Data from Mata LG. The Children of Santa Maria Cauque: A Prospective Field Study of Health and Growth. Cambridge, MA, MIT Press, 1978.)*

Other aspects of the epidemiology of shigellosis elude simple explanation. The seasonality (summer-fall peak in the United States, rainy season peak in the tropics) is not well explained. The geographic variation in species causing infection likewise is not well understood. In the United States, most *Shigella* infections are caused by *S. sonnei* or, less commonly, *S. flexneri*. In most of the developing world, the relative importance of these two species is reversed, and other *Shigella* serotypes, especially *S. dysenteriae* serotype 1, are identified more frequently. As hygiene improves, the proportion of *S. sonnei* increases, and that of *S. flexneri* decreases [651]. Data from Bangladesh suggest that *S. dysenteriae* is less common in neonates, but *S. sonnei* and *S. boydii* are more common [647].

## Clinical Manifestations

There seem to be some important differences in the relative frequencies of various complications of *Shigella* infection related to age. Some of these differences and estimates are based on data that are undoubtedly compromised by reporting biases. *S. dysenteriae* serotype 1 characteristically causes a more severe illness than other shigellae with more complications, including pseudomembranous colitis, hemolysis, and HUS. Illnesses caused by various *Shigella* serotypes usually are indistinguishable, however, from each other and conventionally are discussed together.

The incubation period of shigellosis is related to the number of organisms ingested, but in general, it is 12 to 48 hours. Volunteer studies have shown that after ingestion, illness may be delayed for 1 week or more. Neonatal shigellosis seems to have a similar incubation period. More than half of neonatal cases occur within 3 days of birth, consistent with fecal-oral transmission during parturition. Mothers of infected neonates are sometimes carriers, although more typically they are symptomatic during the perinatal period. Intrauterine infection is rare. In an older child, the initial signs are usually high fever, abdominal pain, vomiting, toxicity, and large-volume watery stools; diarrhea may be bloody or may become bloody. Painful defecation and severe, crampy abdominal pain associated with frequent passage of small-volume stools with gross blood and mucus are characteristic findings in older children or adults who develop severe colitis. Many children never develop bloody diarrhea, however. Adult volunteer studies have shown that variations in presentation and course are not related to the dose ingested because some patients develop colitis with dysentery, but others develop only watery diarrhea after ingestion of the same inoculum [638].

The neonate with shigellosis may have a mild diarrheal syndrome or a severe colitis [648,652–660]. Fever in neonates is usually low grade (<38.8° C [<102° F]) if the course is uncomplicated. The neonate has less bloody diarrhea, more dehydration, more bacteremia, and a greater likelihood of death than the older child with shigellosis [647]. Physical examination of the neonate may show signs of toxicity and dehydration, although fever, abdominal tenderness, and rectal findings are less striking than in the older child [649].

Complications of shigellosis are common [661]. Although the illness is self-limited in the normal host,

resolution may be delayed for 1 week or more. In neonates and malnourished children, chronic diarrhea may follow a bout of shigellosis [652,660]. Of hospitalized children with *Shigella*, 10% to 35% have convulsions before or during the course of diarrhea [661–663]. Usually, the seizures are brief, generalized, and associated with high fever. Seizures are uncommon in the first 6 months of life, although neonates have been described with seizures [654,664]. The cerebrospinal fluid generally reveals normal values in these children, but a few have mild cerebrospinal fluid pleocytosis. The neurologic outcome generally is good even with focal or prolonged seizures, but fatalities occasionally occur, often associated with toxic encephalopathy [665]. Although the seizures had been postulated to result from the neurotoxicity of Shiga toxin, this explanation was proved to be incorrect because most shigellae make little or no Shiga toxin, and the strains isolated from children with neurologic symptoms do not produce Shiga toxin [631,666]. Hemolysis with or without development of uremia is a complication primarily of *S. dysenteriae* serotype 1 infection [667].

Sepsis during the course of shigellosis may be caused by the *Shigella* itself or by other gut flora that gain access to the bloodstream through damaged mucosa [647,668,669]. The risk of sepsis is higher in the 1st year of life, particularly in neonates [647,652–654,664,670], in malnourished infants, and in infants with *S. dysenteriae* serotype 1 infection [669]. Sepsis may occur in 12% of neonates with shigellosis [646,661,668,671]. Given the infrequency of neonatal shigellosis, it is striking that 9% of reported cases of *Shigella* sepsis have involved infants in the 1st month of life [672]. One of the infants with bacteremia [673] reportedly had no discernible illness. Disseminated intravascular coagulation may develop in patients whose course is complicated by sepsis. Meningitis has been described in a septic neonate. Colonic perforation has occurred in neonates [645,674], older children [675], and adults [676]. Although this complication of toxic megacolon is rare, it seems to be more common in neonates than in older individuals. Bronchopneumonia may complicate the course of shigellosis, but shigellae are rarely isolated from lungs or tracheal secretions [677]. The syndrome of sudden death in the setting of extreme toxicity with hyperpyrexia and convulsions but without dehydration or sepsis (i.e., Ekiri syndrome) [678–680] is rare in neonates. In a nonbacteremic child, other extraintestinal foci of infection, including vagina [681,682] and eye [683], rarely occur. Reiter syndrome, which rarely complicates the illness in children, has not been reported in neonates.

Although infection is less common in infants than in toddlers, case-fatality rates are highest in infants [684,685]. The mortality rate in newborns seems to be about twice that of older children [647]. In industrialized societies, less than 1% of children with shigellosis die, whereas in developing countries, 30% die. These differences in mortality rates are related to nutrition [648], availability of medical care, antibiotic resistance of many shigellae, the frequency of sepsis, and the higher frequency of *S. dysenteriae* serotype 1 infection in the less-developed world [669].

## Diagnosis

Although the diagnosis of shigellosis can be suspected on clinical grounds, other enteropathogens can cause illnesses that are impossible to distinguish clinically. Shigellosis in neonates is rare. A neonate with watery diarrhea is more likely to be infected with *E. coli*, *Salmonella*, or rotavirus than *Shigella*. Infants presenting with bloody diarrhea may have necrotizing enterocolitis or infection with *Salmonella*, EIEC, *Yersinia enterocolitica*, *C. jejuni*, or *Entamoeba histolytica*. Before cultures establish a diagnosis, clinical and laboratory data may aid in making a presumptive diagnosis. Abdominal radiographs showing pneumatosis intestinalis suggest the diagnosis of necrotizing enterocolitis. A history of several weeks of illness without fever and with few fecal leukocytes suggests *E. histolytica*, rather than *Shigella* infection [686].

The definitive diagnosis of shigellosis depends on isolation of the organism from stool. Culture may be insensitive, however [687]. In volunteer studies, daily stool cultures failed to detect shigellae in about 20% of symptomatic subjects [638]. Optimal recovery is achieved by immediate inoculation of stool (as opposed to rectal swabs) onto culture media. Use of transport media generally decreases the yield of cultures positive for *Shigella* [688] compared with immediate inoculation.

Examination of stool for leukocytes as an indication of colitis is useful in support of the clinical suspicion of shigellosis. The white blood cell count and differential count also are used as supporting evidence for the diagnosis. Leukemoid reactions (white blood cells $>50{,}000/mm^3$) occur in almost 15% of children with *S. dysenteriae* serotype 1, but in less than 2% of children with other shigellae [666]. Leukemoid reactions are more frequent in infants than in older children [667]. Even when the total white blood cell count is not dramatically elevated, there may be a striking left shift. Almost 30% of children with shigellosis have greater than 25% bands on the differential cell count [689–691]. Few reports address the white blood cell count in newborns, but those that do suggest that normal or low rather than elevated counts are more common. Although serum and fecal antibodies develop to lipopolysaccharides and virulence plasmid–associated polypeptides [692], serologic studies are not useful in the diagnosis of shigellosis. PCR can identify *Shigella* and EIEC in feces [693]. Colonoscopy typically shows inflammatory changes that are most severe in the distal segments of colon [694].

## Therapy

Because dehydration is particularly common in neonatal shigellosis, attention to correction of fluid and electrolyte disturbances is always the first concern when the illness is suspected. Although debate continues over the indications for antimicrobial therapy in patients with shigellosis, the benefits of therapy generally seem to outweigh the risks. The chief disadvantages of antimicrobial therapy include cost, drug toxicity, and emergence of antibiotic-resistant shigellae. Because of the self-limited nature of shigellosis, it has been argued that less severe illness should not be treated. Children can feel quite ill during the typical bout of shigellosis, however, and appropriate antimicrobial

therapy shortens the duration of illness and eliminates shigellae from stool, decreasing secondary spread. Complications are probably decreased by antibiotics. Given the high mortality rates of neonatal shigellosis, therapy should not be withheld.

The empirical choice of an antimicrobial agent is dictated by susceptibility data for strains circulating in the community at the time the patient's infection occurs. Multiresistant shigellae complicate the choice of empirical therapy before availability of susceptibility data for the patient's isolate. Plasmid-encoded resistance (R factors) for multiple antibiotics has been observed frequently in *S. dysenteriae* serotype 1 outbreaks [695] and with other shigellae [696–698]. Antimicrobial resistance patterns fluctuate from year to year in a given locale [699]. Despite the guesswork involved, early preemptive therapy is indicated, however, when an illness is strongly suggestive of shigellosis. In vitro susceptibility does not always adequately predict therapeutic responses. Cefaclor [700], furazolidone [701], cephalexin [702], amoxicillin [703], kanamycin [704], and cefamandole [705] all are relatively ineffective agents.

The optimal duration of therapy is debatable. Studies in children older than 2 years and in adults suggest that single-dose regimens may be as effective in relieving symptoms as courses given for 5 days. The single-dose regimens generally are not as effective in eliminating shigellae from the feces as the longer courses. A third-generation cephalosporin, such as ceftriaxone, may be the best empirical choice. Optimal doses for newborns with shigellosis have not been established. Trimethoprim at a dose of 10 mg/kg/day (maximum 160 mg/day) and sulfamethoxazole at a dose of 50 mg/kg/day (maximum 800 mg/day) in two divided doses for a total of 5 days are recommended for older children if the organism is susceptible [706–708]. If the condition of the infant does not permit oral administration of the drug, daily therapy usually is divided into three doses given intravenously over 1 hour [709]. Ampicillin at a dose of 100 mg/kg/day in four divided doses taken orally for 5 days may be used if the strain is susceptible [691].

For the rare newborn who acquires shigellosis, appropriate therapy often is delayed until susceptibility data are available. This delay occurs because shigellosis is so rare in newborns that it is almost never the presumptive diagnosis in a neonate with watery or bloody diarrhea. Although a sulfonamide is as efficacious as ampicillin when the infecting strain is susceptible [690], sulfonamides are avoided in neonates because of concern about the potential risk of kernicterus. The risk of empirical ampicillin therapy is that shigellae are frequently resistant to the drug; 50% of shigellae currently circulating in the United States are ampicillin resistant [709,710].

For the neonate infected with ampicillin-resistant *Shigella*, there are few data on which to base a recommendation. Ceftriaxone is generally active against shigellae, but in the neonate, this drug can displace bilirubin-binding sites and elicit clinically significant cholestasis. Data on children and adults suggest that clinical improvement occurs with ceftriaxone [711,712]. Quinolones, such as ciprofloxacin and ofloxacin, have been shown to be effective agents for treating shigellosis [713,714] in adults, but they are not approved by the FDA for use in children younger than 18 years. In severe cases of shigellosis, a quinolone may be considered because the fear of quinolone-associated cartilage damage has decreased over time. Other drugs sometimes used to treat diarrhea pose special risks to the infant with shigellosis. The antimotility agents, in addition to their intoxication risk, may pose a special danger in dysentery. In adults, diphenoxylate hydrochloride with atropine has been shown to prolong fever and excretion of the organism [715]. Cefixime may be an effective oral agent in children [221].

The response to appropriate antibiotic therapy is generally gratifying. Improvement is often apparent in less than 24 hours. Complete resolution of diarrhea may not occur until 1 week or more after the start of treatment. In patients who have severe colitis and patients infected by *S. dysenteriae* serotype 1, the response to treatment is delayed.

### Prevention

For most of the developing world, the best strategy for prevention of shigellosis during infancy is prolonged breast-feeding. Specific antibodies in milk seem to prevent symptomatic shigellosis [81,83]; nonspecific modification of gut flora and the lack of bacterial contamination of human milk also may be important. Breast-feeding, even when other foods are consumed, decreases the risk of shigellosis; children who continue to consume human milk into the 3rd year of life are still partially protected from illness [716]. In the United States, the best means of preventing infection in the infant is good hand hygiene when an older sibling or parent develops diarrhea. Even in unsanitary environments, secondary spread of shigellae can be dramatically decreased by hand hygiene after defecation and before meals [717]. Spread of shigellae in the hospital nursery can presumably be prevented by the use of contact isolation for infants with diarrhea and attention to thorough hand hygiene. Although nursery personnel have acquired shigellosis from infected newborns [698], further transmission to other infants in the nursery, although described [718], is rare. In contrast to *Salmonella*, large outbreaks of nosocomial shigellosis in neonates are rare.

Good hygiene is a particularly difficult problem in day care centers. The gathering of susceptible children, breakdown in hand hygiene, failure to use different personnel for food preparation and diaper changing, and difficulty controlling the behavior of toddlers all contribute to day care–focused outbreaks of shigellosis.

Immunization strategies have been studied since the turn of the 20th century, but no satisfactory vaccine has been developed. Even if immunizations are improved, a role in managing neonates seems unlikely.

## *CAMPYLOBACTER*

### Nature of the Organism

*Campylobacter* was first recognized in an aborted sheep fetus in the early 1900s [719] and was named *Vibrio fetus* by Smith and Taylor in 1919 [720]. This organism subsequently was identified as a major venereally transmitted

cause of abortion and sterility and as a cause of scours in cattle, sheep, and goats [721,722]. It was not until 1947, when it was isolated from the blood culture of a pregnant woman who subsequently aborted at 6 months' gestation, that the significance of *Campylobacter* as a relatively rare cause of bacteremia and perinatal infections in humans was appreciated [723–725]. During the 1970s, *Campylobacter* was recognized to be an opportunistic pathogen in debilitated patients [726,727]. In 1963, *V. fetus* and related organisms were separated from the vibrios (e.g., *V. cholerae* and *Vibrio parahaemolyticus*) and placed in a new genus, *Campylobacter* (Greek word for "curved rod") [729]. Since 1973, several *Campylobacter* species have been recognized as a common cause of enteritis [730–746] and, in some cases, extraintestinal infections.

The genus *Campylobacter* contains 15 species, most of which are recognized as animal and human pathogens. The most commonly considered causes of human disease are *Campylobacter fetus*, *C. jejuni*, *Campylobacter coli*, *Campylobacter lari*, and *Campylobacter upsaliensis* (Table 11–5) [744–746], although *Campylobacter mucosalis* has been isolated from stool of children with diarrhea [747]. DNA hybridization studies have shown that these species are distinct, sharing less than 35% DNA homology under stringent hybridization conditions [748,749].

Strains of *C. fetus* are divided into two subspecies: *C. fetus* subspecies *fetus* and *C. fetus* subspecies *venerealis*. The first subspecies causes sporadic abortion in cattle and sheep [750,751]; in the human fetus and newborn, it causes perinatal and neonatal infections that result in abortion, premature delivery, bacteremia, and meningitis [723–725,750–762]. Outside the newborn period, *Campylobacter* is a relatively infrequent cause of bacteremia, usually infecting patients with impaired host defenses, including elderly or debilitated patients; less frequently, it causes intravascular infection [726–729,763,764].

**TABLE 11–5** *Campylobacter* Species That Infect Humans

| Current Nomenclature | Previous Nomenclature | Usual Disease Produced |
|---|---|---|
| *C. fetus* | *Vibrio fetus* | Bacteremia, meningitis, perinatal infection, intravascular infection |
| | *V. fetus* var. *intestinalis* | |
| | *C. fetus* subsp. *intestinalis* | |
| *C. jejuni* | *Vibrio jejuni* | Diarrhea |
| *C. coli* | *C. fetus* subsp. *jejuni* | Diarrhea |
| *C. lari* | Grouped with *C. jejuni*, nalidixic acid–resistant, thermophilic *Campylobacter*, *C. laridis I* | Diarrhea, bacteremia |
| *C. upsaliensis* | None | Diarrhea, bacteremia |
| *C. hyointestinalis* | None | Diarrhea, bacteremia |
| *C. concisus* | None | Diarrhea |

The most common syndrome caused by a *Campylobacter* species is enteritis. *C. jejuni* and *C. coli* cause gastroenteritis and generally are referred to collectively as *C. jejuni*, although DNA hybridization studies show them to be different. In the laboratory, *C. jejuni* can be differentiated from *C. coli* because it is capable of hydrolyzing hippurate, whereas *C. coli* is not. Most isolates that are associated with diarrhea (61% to 100%) are identified as *C. jejuni* [765–768], and in some cases, individuals have been shown to be simultaneously infected with *C. jejuni* and *C. coli* [766].

Because of the fastidious nature of *C. jejuni*, which is difficult to isolate from fecal flora, its widespread occurrence was not recognized until 1973 [730–746]. Previously called related vibrios by King [763], this organism had been associated with bloody diarrhea and colitis in infants and adults only when it had been associated with a recognized bacteremia [769–771]. In the late 1970s, development of selective fecal culture methods for *C. jejuni* enabled its recognition worldwide as one of the most common causes of enteritis in people of all ages. It is an uncommon infection in neonates, who generally develop gastroenteritis when infected [151,732,772–785]. Bacteremia with *C. jejuni* enteritis also is uncommon [732,773, 778,783,786–792]. Maternal symptoms considered to be related to *C. jejuni* infection generally are mild and include fever (75%) and diarrhea (30%). In contrast to the serious disease in newborns that is caused by *C. fetus*, neonatal infections with *C. jejuni* usually result in a mild illness,* although meningitis occurs rarely [775,783]. Third-trimester infection related to *C. fetus* or *C. jejuni* may result in abortion or stillbirth.

## Pathogenesis

*C. fetus* does not produce recognized enterotoxins or cytotoxins and does not seem to be locally invasive by the Sereny test [727,745]. Instead, these infections may be associated with penetration of the organism through a relatively intact intestinal mucosa to the reticuloendothelial system and bloodstream [727]. Whether this characteristic reflects a capacity to resist serum factors or to multiply intracellularly remains to be determined.

*C. jejuni* is capable of producing illness by several mechanisms. Increasing laboratory evidence suggests that the organisms are invasive and proinflammatory [728], similar to *Shigella* and *Salmonella*, although the mechanisms of these effects are not well understood. These organisms have been shown to produce an LT enterotoxin and a cytotoxin [793–796]. This enterotoxin is known to be a heat-labile protein with a molecular mass of 60 to 70 MDa [793,796]. It shares functional and immunologic properties with cholera toxin and *E. coli* LT. *C. jejuni* and *C. coli* also elaborate a cytotoxin active against numerous mammalian cells [797–799]. The toxin is heat labile, trypsin sensitive, and not neutralized by immune sera to Shiga toxin or the cytotoxin of *Clostridium difficile*. The role of these toxins as virulence factors in diarrheal disease remains unproved [793,798].

*References [772,774,776,777,779–782,785,792].

Several animal models have been tested for use in the study of this pathogen [800]. Potential models for the study of *C. jejuni* enteritis include dogs, which may acquire symptomatic infection [801]; 3- to 8-day-old chicks [802–804]; chicken embryo cells, which are readily invaded by *C. jejuni* [739]; rhesus monkeys [805]; and rabbits by means of the removable intestinal tie adult rabbit technique. An established small mammal model that mimics human disease in the absence of previous treatment or surgical procedure has not been successful in adult mice [806]. An infant mouse model [807,808] and a hamster model [809] of diarrhea seem promising. *C. jejuni* is negative in the Sereny test for invasiveness [810], and most investigators report no fluid accumulation in ligated rabbit ileal loops.

## Pathology

The pathologic findings of *C. fetus* infection in the perinatal period include placental necrosis [724] and, in the neonate, widespread endothelial proliferation, intravascular fibrin deposition, perivascular inflammation, and hemorrhagic necrosis in the brain [811]. A tendency for intravascular location and hepatosplenomegaly in adults infected with *C. fetus* has been shown [727].

The pathologic findings in infants and children infected with *C. fetus* include an acute inflammatory process in the colon or rectum, as evidenced by the tendency for patients to have bloody diarrhea with numerous fecal leukocytes [812]. There also can be crypt abscess formation and an ulcerative colitis or pseudomembranous colitis–like appearance [813,814] or a hemorrhagic jejunitis or ileitis [731,739,815,816]. Mesenteric lymphadenitis, ileocolitis, and acute appendicitis also have been described.

## Epidemiology

Infection with *Campylobacter* species occurs after ingestion of contaminated food, including unpasteurized milk, poultry, and contaminated water [740,817–826]. Many farm animals and pets, such as chickens [827], dogs [828,829], and cats (especially young animals), are potential sources. The intrafamilial spread of infection in households [731,830], the occurrence of outbreaks in nurseries [783,784,831], and the apparent laboratory acquisition of *C. jejuni* [832] all suggest that *C. jejuni* infection may occur after person-to-person transmission of the organism. Outbreaks of *C. jejuni* in the child day care setting are uncommon.

Volunteer studies [833] have shown a variable range in the infecting dose, with many volunteers developing no illness. The report of illness after ingestion of $10^6$ organisms in a glass of milk [742] and production of illness in a single volunteer by 500 organisms [833] substantiate the variation in individual susceptibility. The potential for low-inoculum disease has significant implications for the importance of strict enteric precautions when infected persons are hospitalized, particularly in maternity and nursery areas. When diarrhea in neonates caused by *C. jejuni* has been reported [772–785], maternal-infant transmission during labor has generally been documented [772–777,779–782,784,785]. The Lior serotyping system, restriction length polymorphism, and pulsed-field gel electrophoresis [834] have been used to confirm the identity of the infant and maternal isolates. Most mothers gave no history of diarrhea during pregnancy [776,777,779,780]. Outbreaks have occurred in neonatal intensive care units because of person-to-person spread [834].

The frequency of asymptomatic carriage of *C. jejuni* ranges from 0% to 1.3% [730,731] to 13% to 85% [730,731,746,835–837]. In a cohort study in Mexico, 66% of all infections related to *C. jejuni* were asymptomatic [746]. Infected children, if untreated, can be expected to excrete the organisms for 3 or 4 weeks; however, more than 80% are culture-negative after 5 weeks [735,736]. Asymptomatic excreters pose a significant risk in the neonatal period, in which acquisition from an infected mother can be clinically important [732,774,776,780]. *C. jejuni* has increasingly been recognized as a cause of watery and inflammatory diarrhea in temperate and tropical climates throughout the world. It has been isolated from 2% to 11% of all fecal cultures from patients with diarrheal illnesses in various parts of the world [730–738,742,838–843]. There is a tendency for *C. jejuni* enteritis to occur in the summer in countries with temperate climates [839].

The reservoir of *Campylobacter* is the GI tract of domestic and wild birds and animals. It infects sheep, cattle, goats, antelope, swine, chickens, domestic turkeys, and pet dogs. *C. fetus* often is carried asymptomatically in the intestinal or biliary tracts of sheep and cattle. During the course of a bacteremic illness in pregnant animals, *C. fetus* organisms, which have a high affinity for placental tissue, invade the uterus and multiply in the immunologically immature fetus. Infected fetuses generally are aborted. Whether this organism is acquired by humans from animals or is carried asymptomatically for long periods in humans, who may transmit the organism through sexual contact as apparently occurs in animals, is unclear. It is believed that this subspecies rarely is found in the human intestine and that it is not a cause of human enteritis [739].

*C. fetus* infections predominantly occur in older men with a history of farm or animal exposure and in pregnant women in their third trimester [723,724,730,731]. Symptomatically or asymptomatically infected women may have recurrent abortions or premature deliveries and are the source of organisms associated with life-threatening perinatal infections of the fetus or newborn infant [723,753–762,844]. In several instances of neonatal sepsis and meningitis, *C. fetus* was isolated from culture of maternal cervix or vagina [725,761,809]. A nosocomial nursery outbreak has been associated with carriage in some healthy infants [845]. Other outbreaks have been associated with meningitis [846,847]. Cervical cultures have remained positive in women who have had recurrent abortions and whose husbands have antibody titer elevations [752].

The most commonly incriminated reservoir of *C. jejuni* is poultry [822,826,848,849]. Most chickens in several different geographic locations had numerous (mean $4 \times 10^6$/g) *C. jejuni* in the lower intestinal tract or feces. This occurred in some instances despite the use of tetracycline, to which *Campylobacter* was susceptible in vitro, in the chicken feed [842]. The internal cavities of chickens

remain positive for *Campylobacter* even after they have been cleaned, packaged, and frozen [848]. In contrast to *Salmonella*, *C. jejuni* organisms that survive usually do not multiply to high concentrations [739]. Domestic puppies or kittens with *C. jejuni* diarrhea also can provide a source for spread, especially to infants or small children [731,769,826,850–852].

*C. jejuni* enteritis also has been associated in numerous outbreaks with consumption of unpasteurized milk [739, 823–825,853–855]. In retrospect, the first reported human cases of *C. jejuni* enteritis were probably in a milk-borne outbreak reported in 1946 [856]. Because *Campylobacter* infections of the udder are not seen, milk is probably contaminated from fecal shedding of the organism. These organisms are killed by adequate heating.

Fecally contaminated water is a potential vehicle for *C. jejuni* infections [857]. Several phenotypic and genotypic methods have been used for distinguishing *C. jejuni* strains from animals and humans involved in epidemics [858]. *C. jejuni* is associated with traveler's diarrhea among people traveling from England or the United States [734].

## Clinical Manifestations

Clinical manifestations of infection caused by *Campylobacter* depend on the species involved (see Table 11–5). Human infections with *C. fetus* are rare and generally are limited to bacteremia in patients with predisposing conditions [763,764] or to bacteremia or uterine infections with prolonged fever and pneumonitis that last for several weeks in women during the third trimester of pregnancy. Unless appropriately treated, symptoms usually resolve only after abortion or delivery of an infected infant [723,725,753–762,764]. These infected neonates, who are often premature, develop signs suggesting sepsis, including fever, cough, respiratory distress, vomiting, diarrhea, cyanosis, convulsions, and jaundice. The condition typically progresses to meningitis, which may be rapidly fatal or may result in serious neurologic sequelae [725]. Additional systemic manifestations include pericarditis, pneumonia, peritonitis, salpingitis, septic arthritis, and abscesses [837].

*C. jejuni* infection typically involves the GI tract, producing watery diarrhea or a dysentery-like illness with fever and abdominal pain and stools that contain blood and mucus [729,746,814]. Older infants and children generally are affected, but neonates with diarrhea have been reported. Infection in neonates generally is not clinically apparent or is mild. Stools can contain blood, mucus, and pus [725,735,776,777]; fever often is absent [735,776]. The illness usually responds to appropriate antimicrobial therapy [774,776,830], which shortens the period of fecal shedding [859]. Extraintestinal infections related to *C. jejuni* other than bacteremia are rare, but include cholecystitis [860], urinary tract infection [861], and meningitis [775]. Bacteremia is a complication of GI infection [862], especially in malnourished children [863]. Meningitis that apparently occurs secondary to intestinal infection also has been reported in premature infants who have had intraventricular needle aspirations for neonatal hydrocephalus [725]. Complications in older children and adults that have been associated with *C. jejuni* enteritis include Reiter syndrome [864], Guillain-Barré syndrome [865,866], and reactive arthritis [867,868]. Persistent *C. jejuni* infections have been described in patients infected with HIV [869]. Extraintestinal manifestations generally occur in patients who are immunosuppressed or at the extremes of age [727]. *C. lari* has caused chronic diarrhea and bacteremia in a neonate [870].

## Diagnosis

Most important in the diagnosis of *Campylobacter* infection is a high index of suspicion based on clinical grounds. *C. fetus* and *C. jejuni* are fastidious and may be overlooked on routine fecal cultures. Isolation of *Campylobacter* from blood or other sterile body sites does not represent the same problem as isolation from stool. Growth occurs with standard blood culture media, but it may be slow. In the case of *C. fetus* infecting the bloodstream or central nervous system, blood culture flasks should be blindly subcultured and held for at least 7 days, or the organism may not be detected because of slow or inapparent growth [756]. The diagnosis of *C. fetus* infection should be considered when there is an unexplained febrile illness in the third trimester of pregnancy or in the event of recurrent abortion, prematurity, or neonatal sepsis with or without meningitis. A high index of suspicion and prompt, appropriate antimicrobial therapy may prevent the potentially serious neonatal complications that may follow maternal *C. fetus* infection.

*Campylobacter* is distinguished from *Vibrio* organisms by its characteristics of carbohydrate nonfermentation and by its different nucleotide base composition [729,747–749,752]. *Campylobacter* is 0.2 to 0.5 fm wide and 0.5 to 8 fm long. It is a fastidious, microaerophilic, curved, motile gram-negative bacillus that has a single polar flagellum and is oxidase and catalase positive except for *C. upsaliensis*, which is generally catalase negative or weakly positive. *C. jejuni* and *C. fetus* are separated by growth temperature (*C. fetus* grows best at 25° C, but can be cultured at 37° C; *C. jejuni* grows best at 42° C) and by nalidixic acid and cephalosporin susceptibilities because *C. jejuni* is susceptible to nalidixic acid and resistant to cephalosporins.

*C. jejuni* grows best in a microaerobic environment of 5% oxygen and 10% carbon dioxide at 42° C. It grows on various media, including Brucella and Mueller-Hinton agars, but optimal isolation requires the addition of selective and nutritional supplements. Growth at 42° C in the presence of cephalosporins is used to culture selectively for *C. jejuni* from fecal specimens. In a study of six media, charcoal-based selective media and a modified charcoal cefoperazone deoxycholate agar were the most selective for identification of *Campylobacter* species. Extending the incubation time from 48 to 72 hours led to an increase in the isolation rate regardless of the medium used [871]. Its typical darting motility may provide a clue to identification, even in fresh fecal specimens, when viewed by phase-contrast microscopy [735,872].

When the organism has been cultured, it is presumptively identified by motility and by its curved, sometimes sea gull–like appearance on carbolfuchsin stain. Polymorphonuclear leukocytes are usually found in stools when bloody diarrhea occurs and indicate the occurrence of colitis [776,812]. To avoid potentially serious *C. jejuni*

infection in the newborn, careful histories of any diarrheal illnesses in the family should be obtained, and pregnant women with any enteric illness should have cultures for this and other enteric pathogens. Detection of *C. jejuni* and *C. coli* by PCR has been reported [873] and in the future may be useful for the rapid and reliable identification of this organism.

The differential diagnosis of *C. fetus* infections includes the numerous agents that cause neonatal sepsis or meningitis, especially gram-negative bacilli. Diagnostic considerations for inflammatory or bloody enteritis include necrotizing enterocolitis, allergic proctitis, and *Salmonella*; rarely *Shigella* and other infectious agents occur. Agglutination, complement fixation, bactericidal, immunofluorescence, and ELISA tests have been used for serologic diagnosis of *C. jejuni* infection and to study the immune response, but these assays are of limited value in establishing the diagnosis during an acute infection [745].

## Therapy

The prognosis is grave in newborns with sepsis or meningitis caused by *C. fetus*. In infants with *C. jejuni* gastroenteritis, limited data suggest that appropriate, early antimicrobial therapy results in improvement and rapid clearance of the organism from stool [859]. *Campylobacter* species are often resistant to β-lactams, including ampicillin and cephalosporins [874,875]. Most strains are susceptible to erythromycin, gentamicin, tetracycline, chloramphenicol, and the newer quinolones, although resistance to these agents has been reported [876,877]. A parenteral aminoglycoside seems to be the drug of choice for *C. fetus* infections, pending in vitro susceptibility studies. In the case of central nervous system involvement, cefotaxime and chloramphenicol are potential alternative drugs. Depending on in vitro susceptibilities, which vary with locale, erythromycin is the drug of choice for treating *C. jejuni* enteritis [731,735,736]. If erythromycin therapy is initiated within the first 4 days of illness, a reduction in excretion of the organism and resolution of symptoms occur [859].

Although data regarding treatment of asymptomatic or convalescent carriers are unavailable, it seems appropriate to treat colonized pregnant women in the third trimester of pregnancy when there is a risk of perinatal or neonatal infection. The failure of prophylactic parenteral gentamicin in a premature infant has been documented, followed by successful resolution of symptoms and fecal shedding with erythromycin. Because there seems to be an increased risk of toxicity with erythromycin estolate during pregnancy and infancy [878], other forms of erythromycin should probably be used in these settings. Azithromycin seems to be effective if the organism is susceptible [879]. Strains that are erythromycin resistant often are resistant to azithromycin [880]. *Campylobacter* tends to have higher minimal inhibitory concentrations for clarithromycin than for azithromycin [881].

## Prevention

Contact precautions should be employed during any acute diarrheal illness and until the diarrhea has subsided. Hand hygiene after handling raw poultry and washing cutting boards and utensils with soap and water after contact with raw poultry may decrease risk of infection. Pasteurization of milk and chlorination of water are critical. Infected food handlers and hospital employees who are asymptomatic pose no known hazard for disease transmission if proper personal hygiene measures are maintained. Ingestion of human milk that contains anti–*C. jejuni* antibodies has been shown to protect infants from diarrhea caused by *C. jejuni* [78,882].

# *CLOSTRIDIUM DIFFICILE*

## Nature of the Organism and Pathophysiology

*C. difficile* is a spore-forming, gram-positive, anaerobic bacillus that produces two toxins: enterotoxin that causes fluid secretion (toxin A) and a cytotoxin detectable by its cytopathic effects in tissue culture (toxin B) [151,883]. In the presence of antibiotic pressure, *C. difficile* colonic overgrowth and toxin production occur. Both toxin genes have been cloned and sequenced, revealing that they encode proteins with estimated molecular masses of 308 kDa for toxin A and 270 kDa for toxin B [884].

A wide variety of antibacterial, antifungal, antituberculosis, and antineoplastic agents have been associated with *C. difficile* colitis, although penicillin, clindamycin, and cephalosporins are associated most frequently. Rarely, no precipitating drug has been given [885–889]. *C. difficile* and its toxins can be shown in one third of patients with antibiotic-associated diarrhea and in about 98% of patients with pseudomembranous colitis [890].

## Epidemiology

*C. difficile* can be isolated from soil and frequently exists in the hospital environment. Spores of *C. difficile* are acquired from the environment or by fecal-oral transmission from colonized individuals or from items in the environment, such as thermometers and feeding tubes [891–896]. *C. difficile* has been shown to persist on a contaminated floor for 5 months [892]. Nosocomial spread is related to organisms on the hands of personnel [892,893,897], and to contaminated surfaces, which may serve as reservoirs [898,899]. Although all groups are susceptible to infection, newborns represent a special problem. Less than 5% of healthy children older than 2 years [900] and healthy adults carry *C. difficile* [890], but more than 50% of neonates can be shown to have *C. difficile* and its cytotoxin in their stools, usually in the absence of clinical findings [893,899,901–903].

Infants in neonatal intensive care units have high rates of colonization, in part because of frequent use of antimicrobial agents in these units [902,903]. Clustering of infected infants suggests that much of the colonization of newborn infants represents nosocomial spread [899], rather than acquisition of maternal flora. The number of *C. difficile* organisms present in stools of well infants is similar to that found in older patients with pseudomembranous colitis [903]. The high frequency of colonization has led to justified skepticism about the pathogenic potential of this organism in very young patients [904]. Although some episodes of diarrhea in early infancy may

be caused by *C. difficile* [905], the high frequency of asymptomatic carriage in this age group suggests that neither colonization nor detection of toxin production is sufficient to establish the diagnosis of *C. difficile* diarrhea in an infant. Rather, other etiologies should be comprehensively sought, and *C. difficile* should be implicated in the absence of another pathogen.

## Clinical Manifestations

The usual manifestations of *C. difficile* disease in older children and adults include watery diarrhea, abdominal pain and tenderness, nausea, vomiting, and low-grade fever. Grossly bloody diarrhea is unusual, although occult fecal blood is common. Leukocytosis is present during severe illness. Diarrhea usually begins 4 to 9 days into a course of antimicrobial therapy, but may be delayed until several weeks after completion of the therapeutic course. Usually, the illness is mild and self-limited if the offending drug is discontinued. Severe colitis with pseudomembranes is less common now than in previous years because the risk of diarrhea developing during antimicrobial therapy is recognized and the antimicrobial agent typically is stopped.

It is unclear whether *C. difficile* causes disease in newborns. One study from a newborn intensive care unit suggested that toxin A in stools is associated with an increased frequency of abnormal stools [906].

## Diagnosis

Endoscopic findings of pseudomembranes and hyperemic, friable rectal mucosa suggest the diagnosis of pseudomembranous colitis. Pseudomembranes are not always present in *C. difficile* colitis; mild cases are often described as nonspecific colitis. Several noninvasive techniques are used to establish the diagnosis, including enzyme immunoassay (EIA) for toxin detection and PCR [906–909]. Isolation of *C. difficile* from stool does not distinguish between toxigenic and nontoxigenic isolates. If *C. difficile* is isolated, testing for toxin by cell culture or EIA should be performed to confirm the presence of a toxigenic strain. There are multiple commercially available EIAs that detect either toxin A or both toxins A and B [906–908]. These assays are sensitive and easy to perform. Other assays are available for epidemiologic investigation of outbreaks of disease caused by *C. difficile* [909].

In older children and adults, the diagnosis is confirmed by culture of *C. difficile* and demonstration of toxin in feces. In neonates, these data are inadequate to prove that an illness is related to *C. difficile*. When the clinical picture is consistent, the stool studies are positive for *C. difficile*, and no other cause for illness is found, a diagnosis of “possible” *C. difficile* is made. A favorable response to eradication of *C. difficile* is supportive evidence that the diagnosis is correct [885]. Because of the uncertainty implicit in the ambiguity of neonatal diagnostic criteria, other diagnoses must be considered.

## Therapy

When the decision is made that a neonate’s illness might be related to *C. difficile*, the initial approach should include fluid and electrolyte therapy and discontinuation of the offending antimicrobial agent. If the illness persists or worsens or if the patient has severe diarrhea, specific therapy with metronidazole [899,910], should be instituted. Metronidazole is considered to be the treatment of choice for most patients with *C. difficile* colitis [911]. Orally administered vancomycin or bacitracin rarely needs to be considered in neonates [912,913].

After initiation of therapy, signs of illness generally resolve within several days, titers decrease, and fecal toxins disappear eventually. Recurrence of colitis after discontinuation of metronidazole or vancomycin has been documented in 10% to 20% of adults [914]. Relapses are treated with a second course of metronidazole or vancomycin. Drugs that decrease intestinal motility should not be administered.

Neutralizing antibody against *C. difficile* cytotoxin has been shown in human colostrum [915]. Secretory component of IgA binds to toxin A to inhibit its binding to receptors [916]. Data show that there are nonantibody factors present in milk that interfere with the action of toxin B in addition to secretory IgA directed at toxin A [917]. Breast-feeding seems to decrease the frequency of colonization by *C. difficile* [918].

## Prevention

In addition to standard precautions, contact precautions are recommended for the duration of illness. Meticulous hand hygiene techniques, proper handling of contaminated waste and fomites, and limiting the use of antimicrobial agents are the best available methods for control of *C. difficile* infection.

# *VIBRIO CHOLERAE*

## Nature of the Organism

*V. cholerae* is a gram-negative, curved bacillus with a polar flagellum. Of the many serotypes, only enterotoxin-producing organisms of serotype O1 and O139 cause epidemics. *V. cholerae* O1 is divided into two serotypes, Inaba and Ogawa, and two biotypes, classic and E1 Tor; the latter is the predominant biotype. Nontoxigenic O1 strains and non-O1 strains of *V. cholerae* can cause diarrhea and sepsis, but do not cause outbreaks [919–921].

## Pathogenesis

*V. cholerae* O group 1 is the classic example of an enteropathogen whose virulence is caused by enterotoxin production. Cholera toxin is an 84-MDa protein whose five B subunits cause toxin binding to the enterocyte membrane ganglioside $GM_1$ and whose A subunit causes adenosine diphosphate ribosylation of a guanosine triphosphate–binding regulatory subunit of adenylate cyclase [121,921]. The elevated cAMP levels that result from stimulation of enterocytes by cholera toxin cause secretion of salt and water with concomitant inhibition of absorption. Two other toxins are also encoded within the virulence cassette that encodes cholera toxin. These toxins, zona occludens toxin (zot) and accessory cholera toxin (ace), are consistently found in illness-causing strains of O1 and O139, but not usually in *V. cholerae* organisms that are less virulent.

## Epidemiology

Since 1960, *V. cholerae* O1, biotype *El Tor*, has spread from India and Southeast Asia to Africa; the Middle East; southern Europe; and the southern, western, and central Pacific islands (Oceania). In late January 1991, toxigenic *V. cholerae* O1, serotype Inaba, biotype *El Tor*, appeared in several coastal cities of Peru [920,921]. It rapidly spread to most countries in South and North America. In reported cases, travel from the United States to Latin America or Asia and ingestion of contaminated food transported from Latin America or Asia have been incriminated. *V. cholerae* O139 (Bengal) arose on the Indian subcontinent as a new cause of epidemic cholera in 1993 [922–927]. It rapidly spread through Asia and continues to reemerge periodically as a cause of epidemic cholera.

In the United States, an endemic focus of a unique strain of toxigenic *V. cholerae* O1 exists on the Gulf Coast of Louisiana and Texas [919,927,928], This strain is different from the one associated with the epidemic in South America. Most cases of disease associated with the strain endemic to the U.S. Gulf Coast have resulted from the consumption of raw or undercooked shellfish. Humans are the only documented natural host, but free-living *V. cholerae* organisms can exist in the aquatic environment. The usual reported vehicles of transmission have included contaminated water or ice; contaminated food, particularly raw or undercooked shellfish; moist grains held at ambient temperature; and raw or partially dried fish. The usual mode of infection is ingestion of contaminated food or water. Boiling water or treating it with chlorine or iodine and adequate cooking of food kill the organism [920]. Asymptomatic infection of family contacts is common, but direct person-to-person transmission of disease has not been documented. Individuals with low gastric acidity are at increased risk for cholera infection.

## Clinical Manifestations

Cholera acquired during pregnancy, particularly in the third trimester, is associated with a high incidence of fetal death [929]. Miscarriage can be attributed to fetal acidosis and hypoxemia resulting from the marked metabolic and circulatory changes that this disease induces in the mother. The likelihood of delivering a stillborn infant is closely correlated with the severity of the maternal illness. The inability to culture *V. cholerae* from stillborn infants of infected mothers, together with the usual absence of bacteremia in cholera, suggests that transplacental fetal infection is not a cause of intrauterine death.

Neonatal cholera is a rare disease. This generalization also applies to the new O139 strains, although mild [930] and severe forms of illness have rarely been described in newborns [931]. Among 242 neonates admitted to a cholera research hospital in Dacca, Bangladesh, 25 infants were ill with cholera [932]. Even infants born to mothers with active diarrheal disease may escape infection, despite evidence that rice-water stools, almost certain to be ingested during the birth process, may contain $10^9$ organisms/mL [932]. The reason for this apparently low attack rate among newborns is unknown; however, it probably can be attributed in large part to the protection conferred by breast-feeding [933]. Human milk contains antibodies [77] and receptor-like glycoprotein that inhibit adherence of *V. cholerae* [79] and gangliosides that bind cholera toxin [80]. The role of transplacentally acquired vibriocidal maternal antibodies has not been determined [934]. Because *V. cholerae* causes neither bacteremia nor intestinal invasion, protection against illness is more likely to be a function of mucosal rather than serum antibodies [935,936]. Additional factors that may reduce the incidence of neonatal cholera include the large inoculum required for infection [937] and the limited exposure of the newborn to the contaminated food and water [246].

## Diagnosis

Clinicians should request that appropriate cultures be performed for stool specimens from patients suspected to have cholera. The specimen is plated on thiosulfate citrate bile salts sucrose agar directly or after enrichment in alkaline peptone water. Isolates of *V. cholerae* should be confirmed at a state health department and sent to the CDC for testing for production of cholera toxin. A fourfold increase in vibriocidal antibody titers between acute and convalescent serum samples or a fourfold decline in titers between early and late (>2 months) convalescent serum specimens can confirm the diagnosis. Oligonucleotide probes have been developed to test for the cholera toxin gene [938,939],

## Therapy and Prevention

The most important modality of therapy is administration of oral or parenteral rehydration therapy to correct dehydration and electrolyte imbalance and maintain hydration [920]. Antimicrobial therapy can eradicate vibrios, reduce the duration of diarrhea, and reduce requirements for fluid replacement. One cholera vaccine, which is administered parenterally, is licensed in the United States, but is of very limited value. Several experimental oral vaccines are being tested [940–942].

# *YERSINIA ENTEROCOLITICA*

## Nature of the Organism, Epidemiology, and Pathogenesis

*Y. enterocolitica* is a major cause of enteritis in much of the industrialized world [943,944], Enteritis caused by this organism primarily occurs in infants and young children, and infections in the United States are reported to be more common in the North than in the South [945–950]. Animals, especially swine, have been shown to serve as the reservoir for *Y. enterocolitica*. A history of recent exposure to chitterlings (i.e., pig intestine) is common. Transmission has also occurred after ingestion of contaminated milk and infusion of contaminated blood products [951,952],

Virulence of *Y. enterocolitica* is related primarily to a virulence plasmid, which is closely related to the virulence plasmids of *Yersinia pseudotuberculosis* and *Yersinia pestis* [953,954]. ST enterotoxin, which is closely related to ST of ETEC [955], may also be important.

## Clinical Manifestations

Infection with *Y. enterocolitica* is recognized as one of the causes of bacterial gastroenteritis in young children, but knowledge of neonatal infection with this organism is fragmentary. Even in large series, *Yersinia* is rarely isolated from newborns [943,944,956].

The youngest infants whose clinical course has been described in detail were 11 days to several months old at the onset of illness [944,956–964]. There were no features of the gastroenteritis to distinguish it from gastroenteritis caused by other invasive enteric pathogens, such as *Shigella* or *Salmonella*. Infants presented with watery diarrhea or with stools containing mucus with streaks of blood. Sepsis was common in these infants, particularly in the first 3 months of life when 28% of enteritis was complicated by sepsis [960,961,965,966]. Fever is an inconsistent finding in children with bacteremia, and meningitis is rare. In older children, fever and right lower quadrant pain mimicking appendicitis are often found [952].

## Diagnosis

*Y. enterocolitica* can be recovered from throat swabs, mesenteric lymph nodes, peritoneal fluid, blood, and stool. Because laboratory identification of organisms from stool requires special techniques, laboratory personnel should be notified when *Yersinia* is suspected. Because avirulent environmental isolates occur, biotyping and serotyping are useful in assessing the clinical relevance of isolates. PCR has been used to detect pathogenic strains [967,968].

## Therapy

The effect of antimicrobial therapy on the outcome of GI infection is uncertain. It has been recommended that antibiotics be reserved for sepsis or prolonged and severe gastroenteritis [943]; however, there are no prospective studies comparing the efficacy of various antimicrobial agents with each other or with supportive therapy alone. Most strains of *Y. enterocolitica* are susceptible to trimethoprim-sulfamethoxazole, aminoglycosides, piperacillin, imipenem, third-generation cephalosporins, amoxicillin-clavulanate potassium, and chloramphenicol and are resistant to amoxicillin, ampicillin, carbenicillin, ticarcillin, and macrolides [969–971]. Therapy in individual cases should be guided by in vitro susceptibility testing, although cefotaxime has been used successfully in bacteremic infants [966].

# *AEROMONAS HYDROPHILA*

## Nature of the Organism, Epidemiology, and Pathogenesis

*Aeromonas hydrophila* is widely distributed in animals and the environment. Although wound infection, pneumonia, and sepsis (especially in immunocompromised hosts) represent typical *Aeromonas* infections, gastroenteritis increasingly is being recognized. The organism is a gram-negative, oxidase-positive, facultatively anaerobic bacillus belonging to the family Vibrionaceae. Similar to other members of this family, it produces an enterotoxin [972] that causes fluid secretion in rabbit ileal loops [973]. Some strains cause fluid accumulation in the suckling mouse model [974], whereas other strains are invasive [975] or cytotoxic [976]. The enterotoxin is not immunologically related to cholera toxin or the heat LT of *E. coli* [977].

Although volunteer studies and studies with monkeys have failed to provide supportive evidence for enteropathogenicity [978,979], there is good reason to believe that *A. hydrophila* does cause diarrhea in children. The earliest description of *Aeromonas* causing diarrhea was an outbreak that occurred in a neonatal unit [980]. Although several studies have failed to show an association with diarrhea [981–986], most studies have found more *Aeromonas* isolates among children with gastroenteritis than among controls [986–988]. Part of the controversy may be caused by strain differences; some strains possess virulence traits related to production of gastroenteritis, whereas others do not [982,989].

The diarrhea described in children occurs in summer, primarily affecting children in the first 2 years of life. In one study, 7 (13%) of 55 cases of *Aeromonas* detected during a 20-month period occurred in infants younger than 1 month.

## Clinical Manifestations

Typically, watery diarrhea with no fever has been described; although there are descriptions of watery diarrhea with fever [990]. A dysentery-like illness occurred in 22%, however. Dysentery-like illness has been described in neonates [991]. In one third of children, diarrhea has been reported to last for more than 2 weeks [982]. There may be species-related differences in clinical features of Aeromonas-associated gastroenteritis in children [992]. Organisms that were formerly classified as *A. hydrophila* are now sometimes labeled as *Aeromonas sobria* or *Aeromonas caviae* [993, 994], Fever and abdominal pain seem to be particularly common with *A. sobria*. One series of *A. hydrophila* isolates from newborns in Dallas, Texas, showed more blood cultures than stool cultures positive for *Aeromonas* [995].

## Diagnosis and Therapy

Enteric infection associated with *Aeromonas* often is not diagnosed because this organism is not routinely sought in stool cultures. When the organism is suspected, the laboratory should be notified so that oxidase testing can be performed. The organism is usually susceptible to aztreonam, imipenem, meropenem, third-generation cephalosporins, trimethoprim-sulfamethoxazole, and chloramphenicol [996–998].

# *PLESIOMONAS SHIGELLOIDES*

*Plesiomonas shigelloides* is a gram-negative, facultative anaerobic bacillus that, similar to *Aeromonas*, is a member of the Vibrionaceae family. It is widely disseminated in the environment; outbreaks of disease are usually related to ingestion of contaminated water or seafood [999]. Although it has been associated with outbreaks of diarrheal disease [1000] and has been found more commonly in ill than well controls, the role of *P. shigelloides* in

diarrheal disease has remained controversial [1001]. If it is a true enteropathogen, the mechanism by which it causes disease is unclear [1002,1003]. The role of this organism in neonatal diarrhea has not been extensively investigated. Infections of neonates have been reported [1004–1007], but most cases of enteric disease currently reported in the United States are in adults [999]. Typical illness consists of watery diarrhea and cramps; sometimes, fever, bloody stools, and emesis occur and last 3 to 42 days.

Diagnosis is not usually made by clinical microbiology laboratory testing because, as with *Aeromonas*, coliforms can be confused with *P. shigelloides* unless an oxidase test is performed [1008]. The true frequency of infection is unknown. The organism has antibiotic susceptibilities similar to *Aeromonas* [1009,1010],

## OTHER BACTERIAL AGENTS AND FUNGI

Proving that an organism causes diarrhea is difficult, particularly when it may be present in large numbers in stools of healthy people. Bacteria that have been associated with acute gastroenteritis may be considered causative when the following criteria are met:

1. A single specific strain of the organism should be found as the predominant organism in most affected infants by different investigators in outbreaks of enteric disease in different communities.
2. This strain should be isolated in a significantly lower percentage and in smaller numbers from stool specimens of healthy infants.
3. Available methods must be used to exclude other recognized enteropathogens, including viruses and parasites, enterotoxigenic agents, and fastidious organisms such as *Campylobacter*.
4. Demonstration of effective specific antimicrobial therapy and specific antibody responses and, ultimately, production of experimental disease in volunteers are helpful in establishing the identity of a microorganism as a pathogen.

Optimally, the putative pathogen should have virulence traits that can be shown in model systems. Most bacteria that have been suggested as occasional causes of gastroenteritis in neonates fail to fulfill one or more of these criteria. Their role in the cause of diarrheal disease is questionable. This is particularly true of microorganisms described in early reports in which the possibility of infection with more recently recognized agents could not be excluded. Much of the clinical, bacteriologic, and epidemiologic data collected earlier linking unusual enteropathogens to infantile diarrhea must be reevaluated in light of current knowledge and methodology.

Several reports of acute gastroenteritis believed to have been caused by *Klebsiella* suggest that, rather than playing an etiologic role, these organisms had probably proliferated within an already inflamed bowel [1011–1013]. The recovery of *Klebsiella-Enterobacter* in pure culture from diarrheal stools has led several investigators to suggest that these bacteria may occasionally play a causative role in infantile gastroenteritis and enterocolitis [1014–1019]. Ingestion of infant formula contaminated with *Enterobacter sakazakii* has been associated with development of bloody diarrhea and sepsis [1020]. *Klebsiella* species also may be isolated in pure culture from stools of newborns with no enteric symptoms, however [1021–1023]. In one study, certain capsular types of *Klebsiella* were more often isolated from infants with diarrheal disease than from normal infants [1014]. Later work has shown that *Klebsiella pneumoniae*, *Enterobacter cloacae*, and *Citrobacter* species are capable of producing enterotoxins.* Reports of isolation of *Citrobacter* species, describe associations with enteric illnesses in 7% of cases [1026–1028]. There is inadequate evidence to define the roles of *Klebsiella*, *Enterobacter*, and *Citrobacter* species as etiologic agents of enteric illnesses.

*Listeria monocytogenes*, a classic cause of neonatal sepsis and meningitis (see Chapter 13), has been linked to outbreaks of febrile diarrheal disease in immunocompetent adults and children [1029–1033]. Fever has occurred in 72% of ill individuals [1034]. Outbreaks have been related to ingestion of contaminated foods. *Listeria* has rarely been described as a cause of neonatal gastroenteritis [1035–1038].

Infection with enterotoxin-producing *Bacteroides fragilis* has been associated with mild watery diarrhea [1039]. These infections have a peak incidence in children 2 to 3 years old [1040]. These toxin-producing organisms cannot be detected in routine hospital laboratories.

Various organisms have been isolated from infant stools during episodes of diarrhea. Most of these reports have failed to associate illness with specific organisms in a way that has stood the test of time. *P. aeruginosa* [1041–1046] and *Proteus* [1029,1047–1053], have been associated with diarrhea, but there are few convincing data suggesting that either organism is a true enteropathogen. These organisms generally are recovered as frequently from healthy infants as from infants with diarrheal disease, suggesting that their presence in stool cultures is insignificant [289,1054–1058]. An association between *Providencia* and neonatal enteritis has been substantiated largely by anecdotal reports of nursery outbreaks [232,287,1028,1059]. These bacteria are rarely isolated from infants with sporadic or community-acquired diarrheal disease [1054–1056,1060–1062],

*Candida albicans* usually is acquired during passage through the birth canal and is considered a normal, although minor, component of the fecal flora of the neonate (see Chapter 33) [1063]. Intestinal overgrowth of these organisms frequently accompanies infantile gastroenteritis [1063,1064], particularly after antimicrobial therapy [1064–1067]. The upper small gut may become colonized with *Candida* in malnourished children with diarrhea [1068]; whether the presence of the organism is cause or effect is unclear. Stool cultures obtained from infants with diarrheal disease are inconclusive, and although *Candida* enteritis has been reported in adults [1069], the importance of this organism as a primary cause of neonatal gastroenteritis has been difficult to prove. Clinical descriptions of nursery epidemics of

*References [156,183,184,191,209,1020,1024,1025].

candidal enteritis are poorly documented, generally preceding the recognition of EPEC and rotaviruses as a cause of neonatal diarrhea. Even well-studied cases of intestinal involvement add little in the way of substantive proof because secondary invasion of *Candida* has been shown to be a complication of coliform enteritis [228,250,264].

Although diarrhea has sometimes been described as a finding in neonatal disseminated candidiasis, more typically, GI tract involvement with disseminated *Candida* is associated with abdominal distention and bloody stools mimicking necrotizing enterocolitis [264,1068–1073]. Typically, affected infants are premature and have courses complicated by antibiotic administration, intravascular catheter use, and surgical procedures during the first several weeks of life. A trial of oral anticandidal therapy may be helpful in neonates with diarrhea in the presence of oral or cutaneous candidiasis. If the therapy is appropriate, a response should be forthcoming within 2 to 5 days.

Diarrhea sometimes occurs as a manifestation of systemic infection. Patients with staphylococcal toxic shock syndrome often have diarrhea. Loose stools sometimes occur in sepsis, but it is unclear whether the diarrhea is a cause or an effect. The organisms isolated from blood cultures in a group of Bangladeshi infants and children with diarrhea included *Staphylococcus aureus*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, *P. aeruginosa*, and various gram-negative enteric bacilli [1074]. It is unknown whether the bacteriology of sepsis associated with diarrhea is similar in the well-nourished infants seen in industrialized countries.

## PARASITES

Acute diarrhea associated with intestinal parasites is infrequent during the neonatal period. In areas with high endemicity, infection of the newborn is likely to be associated with inadequate maternal and delivery care, insufficient environmental sanitation, and poor personal hygiene standards. The occurrence of symptomatic intestinal parasitic infection during the first month of life requires acquisition of the parasite during the first days or weeks; the incubation period for *E. histolytica* and *G. lamblia* is 1 to 4 weeks and for *Cryptosporidium parvum* is 7 to 14 days. The newborn can be infected during delivery by contact with maternal feces [1075], in the hospital through contact with the mother or personnel, or in the household through contact with infected individuals in close contact with the infant. Contaminated water can be an important source of infection for *G. lamblia* and *C. parvum*.

### *ENTAMOEBA HISTOLYTICA*

Organisms formerly identified as *E. histolytica* have been reclassified into two species that are morphologically identical but genetically distinct: *E. histolytica* and *E. dispar*. The former can cause acute nonbloody and bloody diarrhea, necrotizing enterocolitis, ameboma, and liver abscess, and the latter is a noninvasive parasite that does not cause disease. Early acquisition of disease tends to be more severe in young infants; rarely, amebic liver abscess and rapidly fatal colitis have been reported in infants [1076–1084]. A 19-day-old infant from India who presented with 10 to 12 episodes of watery and mucous diarrhea, lethargy, jaundice, and mildly elevated liver enzymes has been described; the child recovered completely after 10 days of intravenous omidazole [1076]. Amebic liver abscess can be preceded by diarrhea or have a clinical presentation of fulminant neonatal sepsis [1077]. Asymptomatic colonization of neonates with various species of amebae is common in areas of high endemicity [1085].

Diagnosis can be established by stool examination for cysts and trophozoites and by serologic studies [1086]. Through the use of PCR, isoenzyme analysis, and antigen detection assays, *E. histolytica* and *E. dispar* can be differentiated [1087,1088], Serum antibody assays may be helpful in establishing the diagnosis of amebic dysentery and extraintestinal amebiasis with liver involvement. The efficacy of treatment with metronidazole for colitis or liver abscess has not been established for the newborn period, although this therapy has been used successfully [1078]. Patients with colitis or liver abscess caused by *E. histolytica* are treated also with iodoquinol, as are asymptomatic carriers.

### *GIARDIA LAMBLIA*

*G. lamblia* is a binucleate, flagellated protozoan parasite with trophozoite and cyst stages. It is spread by the fecal-oral route through ingestion of cysts. Child care center outbreaks reflecting person-to-person spread have shown its high infectivity potential [1089–1092]. Food-borne transmission and water-borne transmission also occur. Infection is often asymptomatic or mildly symptomatic; cases of severe symptomatic infection during the immediate newborn period have not been reported. Symptoms in giardiasis are related to the age of the patient: Diarrhea, vomiting, anorexia, and failure to thrive are more common in younger children. Seroprevalence studies showed evidence of past or current *G. lamblia* infection in 40% of Peruvian children by the age of 6 months [1093]. In a study of lactating Bangladeshi mothers and their infants, 82% of women and 42% of infants excreted *Giardia* once during the study; in some infants, this occurred before they were 3 months old [1094]. Of these infected infants, 86% had diarrhea, suggesting that the early exposure to the parasite resulted in disease. In a prospective study of diarrhea conducted in Mexico, infants frequently were infected with *Giardia* from birth to 2 months, with a crude incidence rate of first *Giardia* infection of 1.4 infections per child-year in this age group [10]. The symptom status of these children was not reported, but this study strongly suggests that *G. lamblia* may be more common than currently recognized among newborns living in developing areas.

The diagnosis of giardiasis can be made on the basis of demonstration of antigen by EIA or by microscopy of feces, duodenal fluid, or, less frequently, duodenal biopsy specimen [1095,1096], Breast-feeding is believed to protect against symptomatic giardiasis [10,84,1097], This protection may be mediated by cellular and humoral immunity [82,1098,1099], and nonspecifically by the antigiardial effects of unsaturated fatty acids [1100].

*Giardia* infections causing severe diarrhea may respond to metronidazole or furazolidone [1096].

## *CRYPTOSPORIDIUM*

*C. parvum* is a coccidian protozoon related to *Toxoplasma gondii*, *Isospora belli*, and *Plasmodium* species [1101,1102], The life cycle involves ingestion of thick-walled oocysts; release of sporozoites, which penetrate intestinal epithelium; and development of merozoites. Asexual reproduction and sexual reproduction occur, with the latter resulting in formation of new oocysts that can be passed in stools.

*Cryptosporidium* species are ubiquitous. Infection often occurs in people traveling to endemic areas [1103]. Because *Cryptosporidium* infects a wide variety of animal species, there is often a history of animal contact among infected individuals [1104]. Person-to-person spread, particularly in household contacts [1105–1108] and day care centers [1109,1110], is well documented and suggests that the organism is highly infectious. Water-borne outbreaks of cryptosporidiosis occur and can be of massive proportions [1111].

The clinical manifestations of cryptosporidiosis in immunocompetent individuals resemble *Giardia* infection, but are shorter in duration [1112]; asymptomatic carriage is rare. Symptoms and signs include watery diarrhea, abdominal pain, myalgia, fever, and weight loss.* Infection can occur in all age groups, but is largely concentrated in children older than 1 year [1114]. Infection in the first month of life has been described [1115,1116], Because symptoms resolve before excretion of oocysts ceases, a newborn whose mother has been ill with cryptosporidiosis in the month before delivery might be at risk even if the mother is asymptomatic at the time of the child's birth [1117]. With the increasing frequency of HIV infection, it is likely that women with symptomatic cryptosporidiosis may deliver an infant who will become infected. Infants infected early in life may develop chronic diarrhea and malnutrition [1118].

The diagnosis of cryptosporidiosis is most typically made by examination of fecal smears using Giemsa stain, Ziehl-Neelsen stain, auramine-rhodamine stain, Sheather sugar flotation, an immunofluorescence procedure, a modified concentration-sugar flotation method, or EIA [1119,1120], Multiplex real-time PCR for *E. histolytica*, *G. lamblia*, and *C. parvum* and *Cryptosporidium hominis* may prove to be useful in the future [1121]. Nitazoxanide is effective therapy of immunocompetent adults and children with cryptosporidiosis [1122]. Because illness is usually self-limited in the normal host, attention to fluid, electrolyte, and nutritional status is usually sufficient. Enteric isolation of hospitalized infants with this illness is appropriate because of the high infectivity. Several studies suggest that the risk of infection early in life may be decreased by breast-feeding [1116,1123], Using appropriate filtration systems in areas where water treatment is minimal can have a significant impact in decreasing cases of cryptosporidiosis [1124].

# VIRUSES

## ENTERIC VIRUSES

Viruses that infect the intestinal mucosa and cause primarily gastroenteritis are referred to as enteric viruses; they should not be confused with enteroviruses, members of Picornaviridae family that are associated primarily with systemic illnesses. Enteric viruses include rotaviruses, enteric adenoviruses, human caliciviruses, and astroviruses. Other viruses such as coronaviruses, Breda viruses, pestiviruses, parvoviruses, toroviruses, and picobirnaviruses have been sporadically associated with acute diarrhea, but are currently considered of uncertain relevance. More recently, Bocaviruses have been postulated as potential respiratory and intestinal pathogens, but the latter seems unclear [1125]. Extensive reviews on the role of enteric viruses in childhood diarrhea can be found elsewhere [1126–1129].

All four enteric viruses could conceivably infect the newborn, but the extent of exposure and clinical manifestations are largely unknown for astrovirus, enteric adenovirus, and human caliciviruses. Rotavirus is the most extensively studied enteric virus. Neonatal rotavirus infections have similar virologic and clinical characteristics to infection in older children, although some differences exist.

## ROTAVIRUS

Rotavirus is a 75-nm, nonenveloped virus composed of three concentric protein shells: A segmented genome (11 segments), an RNA-dependent polymerase, and enzymes required for messenger RNA synthesis are located within the inner core. Each segment codes for at least one viral protein (VP). The VP can be part of the structure of the virus, or it may be a nonstructural protein (NSP) required for replication, viral assembly, budding, determination of host range, or viral pathogenesis [1128].

Six distinct rotavirus groups (A through F) have been identified serologically based on common group antigens [1130,1131], of which three (A, B, and C) have been identified in humans [1126]. Because group A rotaviruses represent more than 95% of isolated strains in humans worldwide, further discussion focuses on this group. Group A rotaviruses are subclassified into serotypes based on neutralization epitopes located on the outer capsid. Both rotavirus surface proteins, VP4 and VP7, can induce production of neutralizing antibodies [1132,1133], At least 10 VP7 types (G serotypes: G1 to G6, G8 to G10, and G12) and nine VP4 types (P serotypes: P1A, P1B, P2A, P3, P3B, P4, P5, P8, and P12) have been detected among human rotaviruses [1134,1135]. By sequencing the VP4-coding gene, eight genomic P types (genotypes) have been identified that correspond to one or more of the described P antigenic types (genotype 8 to antigenic type P1A, 4 to P1B, 6 to P2A, 9 to P3, 13 to P3B, 10 to P4, 3 to P5, and 11 to P8) [1128]. Combining G antigenic with P antigenic and genetic typing, a specific rotavirus strain can be identified: P antigenic type (P genetic type), G type. As an example, the human neonatal M37 strain is described as P2A [6], G1.

Five combined GP types—P1A [8], G1; P1B [4], G2; P1A [8], G3; P1A [8], G4; P1A [8], G9—account for more

than 95% of the organisms isolated from children, and of these, P1A [8], G1 represents the most common type [1136]. Isolation of less common types seems to be more frequent among neonates with nosocomial rotavirus infections [1137–1143]. Some of these strains seem to be associated with occurrence of asymptomatic infections, although the existence of naturally acquired asymptomatic strains is controversial. Strains P2A [6], G9; P2A [6], G4; P2A [6], G2; P2A [6], G8; and P8 [11], G10 have been reported [1141–1145] from newborn nurseries, some of which seem to be endemic to the newborn units with high rates of asymptomatic infection [1142–1145], and, less commonly, outbreaks of symptomatic infection [1141]. These findings suggest that specific conditions of the newborn environment (e.g., child, nursery, personnel) may increase the possibility of reassortments between human strains; such strains may persist in these settings possibly through constant transmission involving asymptomatic newborns, adults, and contaminated surfaces. Neonates can also be symptomatically infected with unusual animal-human reassortant strains in areas of poor sanitary conditions [1146].

## Pathogenesis

Although mechanisms involved in rotavirus pathogenesis have been extensively studied, current understanding of the exact mechanisms involved in human disease is only partial and may be subject to significant conceptual modifications as more knowledge is obtained in the future. Rotavirus primarily infects mature enterocytes located in the mid and upper villous epithelium [1147–1151]. Lactase, which is present only on the brush border of the differentiated epithelial cells at these sites, may act as a combined receptor and uncoating enzyme for the virus, permitting transfer of the particles into the cell [1152]. Perhaps for this reason, infection is limited to the mature columnar enterocytes; crypt cells and crypt-derived cuboidal cells, which lack a brush border, seem to be resistant to rotaviral infection [1152,1153]. This concept also may explain why rotavirus infection is less common in infants younger than 32 weeks' gestational age than in more mature infants [1154]; at 26 to 34 weeks' gestational age, lactase activity is approximately 30% of that found in term infants [1155].

The upper small intestine is most commonly involved in rotavirus enteritis, although lesions may extend to the distal ileum and rarely to the colon [1156,1157], Interaction between intestinal cell and rotavirus structural and nonstructural proteins occurs, resulting in death of infected villous enterocytes [1158]. When infected, the villous enterocyte is sloughed, resulting in an altered mucosal architecture that becomes stunted and flattened. The gross appearance of the bowel is usually normal; however, under the dissecting microscope, scattered focal lesions of the mucosal surface are apparent in most cases. Light microscopy also shows patchy changes in villous morphology, compatible with a process of infection, inflammation, and accelerated mucosal renewal. The villi take on a shortened and blunt appearance as tall columnar cells are shed and replaced by less mature cuboidal enterocytes [1148,1150,1159]. Ischemia may also play a role in the loss and stunting of villi [1160] and activation of the enteric nervous system; active secretion of fluid and electrolytes may be another pathogenic mechanism [1161].

During the recovery phase, the enteroblastic cells mature and reconstruct the villous structure. Because of the loss of mature enterocytes on the tips of the villi, the surface area of the intestine is reduced. Diarrhea that occurs may be a result of this decrease in surface area, disruption in epithelial integrity, transient disaccharidase deficiency, or altered countercurrent mechanisms and net secretion of water and electrolytes [1148,1155, 1157,1161–1163]. More recent studies suggest that destruction of mature enterocytes does not seem to be a critical element in the pathogenesis of rotavirus infection. The role of NSP4 as a "viral enterotoxin" after the initial report of an age-dependent diarrhea in CD1 mice by triggering calcium-dependent chloride and water secretion [1164] has been supported by new studies [1165]. The exact mechanism of action of this protein at the intestinal level is only partially understood, but known to be different from the action of bacterial enterotoxins. NSP4 does not cause morphologic damage; it impairs glucose absorption and produces moderate calcium-mediated chloride secretion [1165]. The contribution of this "viral enterotoxin" in human rotavirus–associated diarrhea is unclear [1166,1167].

Rotavirus antigenemia and viremia seem to be common events during rotavirus infection, a concept that revolutionized understanding of this infection [1168]. These events could partly explain the sporadic reports of systemic disease associated with rotavirus intestinal infections mentioned further on. An association between viremia and more severe disease has been suggested, but not sufficiently studied to date [1168–1171].

## Infection and Immunity

Infants with asymptomatic rotavirus infections in the nursery are less likely than uninfected nursery mates to experience severe rotavirus infection later in life [1172,1173]; this finding suggested protective immunity and supported vaccine development. Most studies have indicated that serum and intestinal antirotavirus antibody levels are correlated with protection against infection [1173–1181], although this correlation has not been universal [1182,1183]. Breast-feeding protects against diarrhea and specifically rotavirus disease during the first year of life [62,72], probably including newborns [1161]. The high prevalence of antirotaviral antibodies in colostrum and human milk has been shown by numerous investigators in widely diverse geographic areas [12]. Maternal rotavirus infection or immunization is accompanied by the appearance of specific antibodies in milk, probably through stimulation of the enteromammary immune system [1184–1189]. Of women examined in London, Bangladesh, Guatemala, Costa Rica, and the United States, 90% to 100% had antirotaviral IgA antibodies in their milk for 2 years of lactation [12,1184–1190]. Rotavirus-specific IgG antibodies have been found during the first few postpartum days in about one third of human milk samples assayed [1184,1187], whereas IgM antibodies were detectable in about half [1187].

Glycoproteins in human milk have been shown to prevent rotavirus infection in vitro and in an animal model [1190]. The concentration of one milk glycoprotein, lactadherin, was found to be significantly higher in human milk ingested by infants who developed asymptomatic rotavirus infection than in milk ingested by infants who developed symptomatic infection [59].

## Epidemiology

Rotaviruses probably infect neonates more commonly than previously recognized; most infections seem to be asymptomatic or mildly symptomatic, although symptomatic infections may be more common than previously considered, especially in developing countries [1141–1144,1172,1191–1206]. In a study from India, rotavirus positivity was detected in 56% of symptomatic neonates compared with 45% of asymptomatic neonates [1206]. Rotavirus has a mean incubation period of 2 days, with a range of 1 to 3 days in children and in adults experimentally infected. Fecal excretion of virus often begins a day or so before illness, and maximal excretion usually occurs during the 3rd and 4th days and generally diminishes by the end of the 1st week, although low concentrations of virus have been detected in neonates for 8 weeks [1155,1204–1208].

Rotavirus infections are markedly seasonal (autumn and winter) in many areas of the world, although in some countries seasonality is less striking; the reason for this is unclear [1209–1214]. In nurseries in which persisting endemic infection has permitted long-term surveillance of numerous neonates, rotavirus excretion can follow the seasonal pattern of the community, but can also show no seasonal fluctuation [1215–1217]. It is unclear how units in which infection remains endemic for months or years differ from units with a low incidence of rotavirus. Some nurseries are free of rotavirus infection [1217–1219] or minimally affected [59,1220] whereas others have rotavirus diarrheal disease throughout the year or in outbreaks that involve 10% to 40% of neonates [1141,1154,1196,1197,1221].

Low birth weight does not seem to be an important factor in determining the attack rate among infants at risk, but may be important in mortality [1222]. Infants in premature or special care nurseries, despite their prolonged stays and the increased handling necessary for their care, do not exhibit a higher susceptibility to infection; data regarding shedding of the virus are inconsistent [59,1219].

After infection is introduced into a nursery, rotavirus is likely to spread steadily and remain endemic until the nursery is closed to new admissions or nursing practices permit interruption of the cycle [1223]. Exactly how the virus is introduced and transmitted is uncertain, although limited observations and experience with other types of enteric disease in maternity units suggest several possibilities. The early appearance of virus in stools of some neonates indicates that infection probably was acquired at delivery. Virus particles can be detected on the 1st [59,1204] or 2nd [1217] day of life in many infected infants. By day 3 or 4, most infected infants who will shed virus, with or without signs of illness, are doing so [1192,1204,1217]. The numerous virus particles excreted [1192,1217] suggest a fairly large and early oral inoculum. It is unlikely that contamination from any source other than maternal feces could provide an inoculum large enough to cause infection by the 2nd day.

Transfer of particles from infant to infant on the hands of nursing and medical staff is probably the most important means of viral spread. With $10^8$ to $10^{11}$ viral particles usually present in 1 g of stool, the hands of personnel easily could become contaminated after infection is introduced into a nursery. There are numerous reports of nosocomial and day care center rotavirus gastroenteritis outbreaks that attest to the ease with which this agent spreads through a hospital or institutional setting [1126]. Admission of a symptomatic infant usually is the initiating event, although transfer of a neonate with inapparent infection from one ward to another also has been incriminated. The most important factors influencing the incidence of rotavirus diarrhea in a nursery are the proximity to other newborns and the frequency of hand washing [1205]. During a 4-month study, infants cared for by nursing staff and kept in communal nurseries experienced three epidemics of diarrhea with attack rates of 20% to 50%. During the same period, only 2% of infants rooming in with their mothers became ill, even though they had frequent contact with adult relatives and siblings.

There is no clear evidence of airborne or droplet infection originating in the upper respiratory tract or spread by aerosolization of diarrheal fluid while diapers are changed. Indirect evidence of airborne transmission includes the high infection rate in closed settings, the isolation of the virus from respiratory secretions [1224], and the experimental observation of transmission by aerosol droplets in mice [1225]. The respiratory isolation achieved by placing an infant in a closed incubator is not fully protective, however [1205]. No evidence indicates that transplacental or ascending intrauterine infection occurs. Transmission of virus through contaminated fomites, formula, or food is possible, but has not been documented in newborns. Rotavirus particles have not been found in human milk or colostrum [1186,1190].

## Clinical Manifestations

Exposure of a newborn to rotavirus can result in asymptomatic infection or cause mild or severe gastroenteritis.* Outbreaks with high attack rates as measured by rotavirus excretion have been described, but the extent of symptomatic infection varies.† Severe rotavirus infection is seldom reported during the newborn period [1206,1221], but the extent of underreporting of severe disease, especially in the less developed areas of the world, has not been evaluated.

It has been hypothesized that asymptomatic infections during the newborn period are the result of naturally attenuated strains circulating in this environment. RNA electrophoretic patterns of rotaviruses found in certain

*References [1142,1143,1191,1197,1206,1215,1216,1220,1226].

†References [1193,1195,1204,1206,1217,1221].

nurseries have shown uniform patterns [1198,1200,1202,1226], and it has been suggested that these strains may be attenuated. The presence of unusual antigenic types, such as P2A [6] type, within nurseries also suggests "less virulent strains." At least 10 rotavirus strains were documented to cocirculate in a tertiary care center during a 2-month period [1227], and in a different setting the same rotavirus strains by electropherotype produced asymptomatic infection in neonates and symptomatic infection in older infants [1201]. Newborns within a nursery exposed to a given rotavirus strain can develop symptomatic or asymptomatic infection [1143,1228,1229]. P8 [11], G10 was the most common genotype associated with symptomatic and asymptomatic infections in a tertiary care hospital in India [1206]. Because newborns routinely have frequent relatively loose stools, it is possible that mild diarrhea episodes caused by rotavirus are being wrongly labeled as asymptomatic episodes.

No clinical feature is pathognomonic of rotaviral gastroenteritis. Early signs of illness, such as lethargy, irritability, vomiting, and poor feeding, usually are followed in a few hours by the passage of watery yellow or green stools free of blood but sometimes containing mucus [1205,1230–1232]. Diarrhea usually decreases by the 2nd day of illness and is much improved by the 3rd or 4th day. Occasionally, intestinal fluid loss and poor weight gain may continue for 1 or 2 weeks, particularly in low birth weight infants [1193]. Although reducing substances frequently are present in early fecal samples [191,1154,1194,1205], this finding is not abnormal in neonates, particularly infants who are breast-fed [1233]. Nevertheless, infants with prolonged diarrhea should be investigated for monosaccharide or disaccharide malabsorption or intolerance to cow's milk protein or both [1234]. In a prospective study [1203], 49% of newborns with GI symptoms in a neonatal intensive care unit had rotavirus detected in their stools. Frequent stooling (present in 60%), bloody mucoid stool (42%), and watery stools (24%) were risk factors for a rotavirus infection. Bloody mucoid stools, intestinal dilation, and abdominal distention were significantly more common in preterm infants, but severe outcomes such as necrotizing enterocolitis and death did not differ among infected term and preterm infants.

Longitudinal studies in newborn nurseries and investigations of outbreaks among neonates rarely describe a severe adverse outcome or death [1154,1188,1205]. Because these infants are under constant observation, early detection of excessive fluid losses and the availability of immediate medical care are probably major factors in determining outcome. Rotavirus gastroenteritis causes almost 400,000 infant deaths every year [1235], concentrated largely in the poorest regions of the world. It is likely that in places where hospital-based care is uncommon, rotavirus causes neonatal deaths secondary to dehydration.

Group A rotavirus has been associated with a wide array of diseases in infants and children; Reye syndromes, encephalitis–aseptic meningitis, sudden infant death syndrome, inflammatory bowel disease, and Kawasaki syndrome have been described, but not systematically studied [1126]. Case reports and small case series have associated neonatal rotavirus infection with necrotizing enterocolitis [1236,1237]. Rotavirus infection may play a role in a small proportion of cases of necrotizing enterocolitis, although it probably represents one of many potential triggering factors [1206]. A significant association between neonatal rotavirus infection and bradycardia-apnea episodes was detected in one prospective study [1238]. The possible association between natural rotavirus infection and intussusception [1239–1241] gained support after the association was made between the human-simian reassortant vaccine and intussusception in infants older than 2 months (attributable risk approximately 1:10,000) [1242]. Epidemiologic studies have not shown a temporal correlation between peaks of rotavirus infection and increase in cases of intussusception [1243]. Intussusception is extremely uncommon in the newborn; it is highly unlikely that rotavirus triggers this disease in neonates.

## Diagnosis

There are many methods used for detection of rotavirus in stool specimens, including electron microscopy, immune electron microscopy, ELISA, latex agglutination, gel electrophoresis, culture of the virus, and reverse transcriptase PCR. ELISA and latex agglutination currently are the most widely used diagnostic techniques for detection of rotavirus in clinical samples. Many commercial kits are available that differ in specificity and sensitivity [1244–1248]. Latex agglutination assays generally are more rapid than ELISAs, but are less sensitive. The sensitivity and specificity of commercially available ELISAs surpass 90%. Checking of the ELISA by another method such as gel electrophoresis or PCR amplification may be desirable if there is concern about false-positive results.

Fecal material for detection of rotavirus infection should be obtained during the acute phase of illness. Whole-stool samples are preferred, although suspensions of rectal swab specimens have been adequate for detection of rotavirus by ELISA [1249,1250]. Rotavirus is relatively resistant to environmental temperatures, even tropical temperatures [1251], although 4° C is desirable for short-term storage and −70° C for prolonged storage [1126]. Excretion of viral particles may precede signs of illness by several days [1209]; maximal excretion by older infants and children usually occurs 3 to 4 days after onset of symptoms [1252]. Neonates can shed virus for 1 to 2 weeks after onset of symptoms.

## Therapy and Prevention

The primary goal of therapy is restoration and maintenance of fluid and electrolyte balance. Despite the documented defect in carbohydrate digestion with rotavirus diarrhea, rehydration often can be accomplished with glucose-electrolyte or sucrose-electrolyte solutions given orally [215,1253–1255]. Intravenous fluids may be needed in neonates who are severely dehydrated, who have ileus, or who refuse to feed. Persistent or recurrent diarrhea after introduction of milk-based formulas or human milk warrants investigation for secondary carbohydrate or milk protein intolerance [1154,1235]. Disaccharidase levels and xylose absorption return to normal within a few days [1159] to weeks after infection [1148].

Intractable diarrhea related to severe morphologic and enzymatic changes of the bowel mucosa is possible, although rare in the newborn; it may require an elemental diet or parenteral nutrition. Efficacy of antirotavirus antibodies (e.g., hyperimmune colostrum, antibody-supplemented formula, human serum immunoglobulin) and of probiotics has been postulated [1256–1259], although not convincingly shown [1260]; the widespread clinical use of these measures seems remote. One study suggests that use of lactobacillus during the diarrheal episode may decrease the duration of rotavirus-associated hospital stays, especially when used early in the course of the disease, although more studies are needed before recommending widespread use [1259].

Hand hygiene before and after contact with each infant is the most important means of preventing the spread of infection. Because rotavirus is often excreted several days before illness is recognized, isolation of an infant with diarrhea may be too late to prevent cross-infection, unless all nursing personnel and medical staff have adhered to this fundamental precaution. Infants who develop gastroenteritis should be moved out of the nursery area if adequate facilities are available and the infant's condition permits transfer. The use of an incubator is valuable in reducing transmission of disease only by serving as a reminder that proper hand hygiene and glove techniques are required, but is of little value as a physical barrier to the spread of virus [1205]. Encouraging rooming-in of infants with their mothers has been shown to be helpful in preventing or containing nursery epidemics [1261]. Temporary closure of the nursery may be required for clinically significant outbreaks that cannot be controlled with other measures [1141].

### Vaccines

Development of rotavirus vaccines began in the early 1980s. Candidate vaccines included bovine and rhesus monkey attenuated strains, human attenuated strains, and bovine-human and rhesus-human reassortant strains [1127]. In August 1998, the first licensed rotavirus vaccine, Rotashield, an oral formulation of a simian-human quadrivalent reassortant vaccine, was recommended for use in children when they were 2, 4, and 6 months old. After approximately 500,000 children were vaccinated with more than 1 million doses, a significantly increased risk of intussusception was observed among vaccinated children, with an overall odds ratio of 1.8 [1262]. Use of this vaccine was terminated. Two new vaccines proved to be safe and effective in large phase III trials: a vaccine including five bovine-human reassortant strains including human G types G1-G4 and P type P1A [8] and a vaccine including one human attenuated P1A [8], G1.

These vaccines have a protective efficacy against moderate to severe rotavirus gastroenteritis leading to hospitalizations that surpasses 85%. Protection is broad against the most common serotypes. Key articles and reviews summarizing the studies that support these vaccines can be found elsewhere [1263–1269]. The epidemiology of rotavirus infection is likely to change significantly as these vaccines become widely available; a significant decrease of rotavirus infection has been reported more recently in the United States where one of the vaccines is being used, but more prolonged surveillance is required [1270]. The impact on neonatal infection will depend on the effect of herd immunity in decreasing circulation of rotavirus strains.

## DIFFERENTIAL DIAGNOSIS

Stools from breast-fed neonates are typically watery and yellow, green, or brown. The frequency of stooling can vary from one every other day to eight evacuations per day. In an active, healthy infant who is feeding well, has no vomiting, and has a soft abdomen, these varied patterns of stooling are not a cause for concern. Physicians need to consider the infant's previous frequency and consistency of stools and establish a diagnosis of acute diarrhea on an individual basis. Close follow-up of weight increase in infants with nonformed stools can help confirm the clinical impression. A normal weight gain should direct medical action away from stool examinations or treatment.

Diarrhea during the neonatal period is a clinical manifestation of a wide variety of disorders (Table 11–6). The most common initiating factor is a primary infection of the GI tract that is mild to moderate in severity, self-limited, and responsive to supportive measures. Acute diarrhea can also be an initial manifestation of a systemic infection, including bacterial and viral neonatal sepsis. Infants with moderate to severe diarrhea require close monitoring until the etiologic diagnosis and the clinical evolution are clarified. Noninfectious diseases leading to chronic intractable diarrhea may result in severe nutritional disturbances or even death unless the specific underlying condition is identified and treated appropriately. The differential diagnosis of a diarrheal illness requires a careful clinical examination to determine whether the child has a localized or a systemic process. Lethargy, abnormalities in body temperature, hypothermia or hyperthermia, decreased feeding, abdominal distention, vomiting, pallor, respiratory distress, apnea, cyanosis, hemodynamic instability, hypotension, hepatomegaly or splenomegaly, coagulation or bleeding disorders, petechiae, and exanthemas should lead to an intense laboratory investigation directed at systemic viral or bacterial infection. If the process is deemed a localized intestinal infection, initial evaluation can be focused on differentiating an inflammatory-invasive pathogen from pathogens that cause a noninflammatory process. For this, stool examination for fecal leukocytes, red blood cells, and lactoferrin can be a helpful indicator of the former.

Inflammatory diarrhea can be caused by *Shigella*, *Salmonella*, *Campylobacter*, *V. parahaemolyticus*, *Y. enterocolitica*, EIEC, EAEC, *C. difficile*, necrotizing enterocolitis, antibiotic-associated colitis, and allergic colitis (i.e., milk or soy intolerance). Noninflammatory causes of diarrhea include ETEC, EPEC, rotaviruses, enteric adenoviruses, calicivirus, astrovirus, *G. lamblia*, and *Cryptosporidium*. *V. cholerae* can cause severe life-threatening neonatal diarrhea in regions where the infection is endemic [1271]. Cytomegalovirus can cause mild to severe enteritis that may result in ileal stricture [1272]. Enteroviruses can

*[AIDS, acquired immunodeficiency syndrome].*

cause outbreaks of fever, diarrhea, and respiratory symptoms in newborn units [1273]. Although supportive fluid therapy is mandatory for all types of diarrhea, the brief examination for fecal leukocytes and red blood cells can direct the diagnostic and therapeutic approach. Pathogens such as *Shigella*, *Salmonella*, and EHEC can cause watery or bloody diarrhea, depending on the specific host-pathogen interaction and the pathogenic mechanisms involved. Some noninfectious diseases responsible for neonatal diarrhea are listed in Table 11–6 [355,542,1274–1319]. The evaluation and management of persistent infantile diarrhea has been reviewed [1320].

CHAPTER
12

# GROUP B STREPTOCOCCAL INFECTIONS

Morven S. Edwards · Victor Nizet

CHAPTER OUTLINE

Lancefield group B β-hemolytic streptococci were first recorded as a cause of human infection in 1938, when Fry [1] described three patients with fatal puerperal sepsis. Sporadic cases were reported during the next 3 decades, but this microorganism remained unknown to most clinicians until the 1970s, when a dramatic increase in the incidence of septicemia and meningitis in neonates caused by group B streptococci (GBS) was documented from geographically diverse regions. [2–4] Emergence of group B streptococcal infections in neonates was accompanied by an increasing number of these infections in pregnant women and nonpregnant adults. In pregnant women, infection commonly manifested as localized uterine infection or chorioamnionitis, often with bacteremia, and had an almost uniformly good outcome with antimicrobial therapy. In other adults, who typically had underlying medical conditions, infection often resulted in death [5]. The incidence of perinatal infection associated with GBS remained stable through the early 1990s. Case-fatality rates had declined by then, but remained substantial compared with case-fatality rates reported for other invasive bacterial infections in infants.

Several notable events have occurred in recent years. Capsular type IX has been proposed, bringing the number of types causing invasive human disease to 10 [6]. The complete genomes of types III and V GBS have been sequenced, opening new avenues for the identification of novel potential vaccine targets [7,8]. The discovery that surface-associated pili are widely distributed among GBS and that a vaccine based on combinations of the three pilus-island variants protects mice against lethal challenge with a wide variety of group B streptococcal strains paves the way for the design of pilus-based and perhaps other putative surface protein vaccines for testing in humans [9–11].

The implementation of 2002 consensus guidelines to prevent early-onset disease in neonates through universal antenatal culture screening at 35 to 37 weeks' gestation and intrapartum antibiotic prophylaxis (IAP) has been associated with a substantial decline in the incidence of neonatal infection for the first time in 3 decades [12]. Finally, testing of group B streptococcal candidate vaccines in healthy adults has been achieved, offering promise that immunization to prevent maternal and infant and perhaps adult invasive group B streptococcal disease could become a reality.

## ORGANISM

*Streptococcus agalactiae* is the species designation for streptococci belonging to Lancefield group B. This bacterium is a facultative gram-positive diplococcus with an ultrastructure similar to that of other gram-positive cocci. Before Lancefield's classification of hemolytic streptococci in 1933 [13], this microorganism was known to microbiologists by its characteristic colonial morphology,

DOI: 10.1016/B978-1-4160-6400-8.00012-2

its narrow zone of β-hemolysis surrounding colonies on blood agar plates, and its double zone of hemolysis that appeared when plates were refrigerated an additional 18 hours beyond the initial incubation [14]. Occasional strains (approximately 1%) are designated α-hemolytic or nonhemolytic. GBS are readily cultivated in various bacteriologic media. Isolation from certain body sites (respiratory, genital, and gastrointestinal tracts) can be enhanced by use of broth medium containing antimicrobial agents that inhibit growth of other bacterial species indigenous to these sites [15,16].

## COLONIAL MORPHOLOGY AND IDENTIFICATION

Colonies of GBS grown on sheep blood agar medium are 3 to 4 mm in diameter, produce a narrow zone of β-hemolysis, are gray-white, and are flat and mucoid. β-hemolysis for some strains is apparent only when colonies are removed from the agar.

Tests for presumptive identification include bacitracin and sulfamethoxazole-trimethoprim disk susceptibility testing (92% to 98% of strains are resistant), hydrolysis of sodium hippurate broth (99% of strains are positive), hydrolysis of bile esculin agar (99% to 100% of strains fail to react), pigment production during anaerobic growth on certain media (96% to 98% of strains produce an orange pigment), and CAMP (Christie-Atkins-Munch-Petersen) testing (98% to 100% of strains are CAMP-positive) [17–19]. The CAMP factor is a thermostable extracellular protein that, in the presence of the β toxin of *Staphylococcus aureus*, produces synergistic hemolysis when grown on sheep blood agar. Hippurate hydrolysis is an accurate method for presumptive identification of GBS, but the requirement for 24 to 48 hours of incubation limits its usefulness. GBS can be differentiated from other streptococci by a combination of the CAMP test, the bile esculin reaction, and bacitracin sensitivity testing [17]. Biochemical micromethods identify GBS with reasonable accuracy after a 4-hour incubation period [20].

Definitive identification of GBS requires detection of the group B–specific antigen common to all strains through use of hyperimmune grouping antiserum. Lancefield's original method required acid treatment of large volumes of broth-grown cells to extract the group B antigen from the cell wall [21]. Supernatants were brought to neutral pH and mixed with hyperimmune rabbit antiserum prepared by immunization with the group B–variant strain (090R) (devoid of type Ia–specific antigen), and precipitins in capillary tubes were recorded. Less time-consuming serologic techniques are now employed, but all use group-specific antiserum to identify the group B antigen in intact cells, broth culture supernatants, or cell extracts. Commercial availability and simplicity make latex agglutination–based assays the most practical and frequently used methods by hospital laboratories [22]. Real time reverse transcriptase polymerase chain reaction (RT-PCR) methods have been developed more recently for grouping of clinical specimens, and PCR has been developed for genotyping of group B streptococcal isolates.

## STRAINS OF HUMAN AND BOVINE ORIGIN

GBS were known to cause bovine mastitis before they were appreciated as pathogenic in humans [23]. Modern veterinary practices have largely controlled epidemics of bovine mastitis, but sporadic cases still occur. Substantial biochemical, serologic, and molecular differences exist between human and bovine isolates [24,25]. Among typable bovine strains, patterns of distribution distinct from the patterns of human isolates are noted. Other distinguishing characteristics for bovine strains include their unique fermentation reactions, their decreased frequency of pigment production, and their usual susceptibility to bacitracin. Protein X, rarely found in human strains, is commonly present in pathogenic bovine isolates [26].

## CLASSIFICATION

Lancefield defined two cell wall carbohydrate antigens employing hydrochloric acid–extracted cell supernatants and hyperimmune rabbit antisera: the group B–specific or "C" substance common to all strains and the type-specific or "S" substance that allowed classification into types, initially types I, II, and III [27–29]. Strains designated as type I were later shown to have cross-reactive and antigenically distinct polysaccharides, and the antigenically distinct type Ia and type Ib polysaccharides were defined [28]. GBS historically designated type Ic were characterized when strains possessing type Ia capsular polysaccharide (CPS) were shown also to possess a protein antigen common to type Ib, most type II, and rarely type III strains [30]. This protein, originally called the "type Ib/c antigen," now is known as C protein. Rabbit antibodies directed against CPS protected mice against lethal challenge with homologous, but not heterologous, group B streptococcal types, and cross-protection was also afforded when antibodies against C protein were tested.

Current nomenclature designates polysaccharide antigens as type antigens and protein antigens as additional markers for characterization [31,32]. The former type Ic now is designated type Ia/c. Type IV was identified as a new type in 1979, when 62 strains were described that possessed type IV polysaccharide alone or with additional protein antigens [33]. Antigenically distinct types, V through IX, now are characterized. Strains not expressing one of the CPS-specific antigens are designated as nontypable by serologic methods, but often can be characterized by PCR-based methods.

Characterization of C protein showed that it is composed of two unrelated protein components, the trypsin-resistant α C protein and the trypsin-sensitive β C protein [34]. α C protein is expressed on many type Ia, Ib, and II strains [34]. Strains expressing α C protein are less readily opsonized, ingested, and killed by human polymorphonuclear leukocytes in the absence of specific antibody than are α C–negative strains [35]. α C protein consists of a series of tandem repeating units, and in naturally occurring strains, the repeat numbers can vary. The number of repeating units expressed alters antigenicity and influences the repertoires of antibodies elicited [36]. The use of one or two repeat units of α C proteins elicits antibodies that bind all α C proteins with equal affinity, suggesting its potential as a vaccine candidate [37,38].

β C protein is a single protein with a molecular mass of 124 to 134 kDa that is present in about 10% of isolates. β C protein binds the Fc region of human IgA [39–41]. Strains bearing α and β C proteins possess increased resistance to opsonization in vitro.

GBS express numerous additional surface proteins. Designation of additional α-like repetitive proteins (Alp) numerically (e.g., Alp2 and Alp3) is being considered. Most group B streptococcal strains have the gene for just one of the Alp family proteins. Genes encoding Alp1 (also designated "epsilon") are associated with type Ia, and genes encoding Alp3 are associated with type V strains [42]. Alp also are referred to as R proteins, of which R1 and R4 are the major ones found on clinical isolates [42]. Rib protein, expressed by most type III strains, has been shown to have an identical sequence to R4. The gene sequence of a protein initially designated R5 that is expressed by numerous clinically relevant group B streptococcal types has been sequenced and renamed group B protective surface protein [43]. Some GBS contain surface proteins designated as X antigens. These were first described by Pattison and coworkers [44], who introduced reagents for their detection in an attempt to classify nontypable strains further. The X and R antigens are immunologically cross-reactive. A laddering protein from type V GBS shares sequence homology with α C protein [45]. A protein designated Sip (for surface immunogenic protein) is distinct from other known surface proteins. It is produced by all serotypes of GBS and confers protection against experimental infection; its role in human infection is unknown [46].

Genome analysis has revealed that GBS produce long pilus-like structures. These structures extend from the bacterial surface and beyond CPS (Fig. 12–1) [9]. Formed by proteins with adhesive functions, these structures are implicated in host colonization, attachment, and invasion [47]. The pilus-like structures are encoded in genomic pilus islands that have an organization similar to that of pathogenicity islands. Three types of pilus island have been identified through genomic analysis; these are composed of partially homogeneous covalently linked proteins (pilus islands 1, 2a, and 2b). These pili proteins are highly surface-expressed and are involved in paracellular translocation through epithelial cells. At least one of these is present on all group B streptococcal clinical strains tested to date.

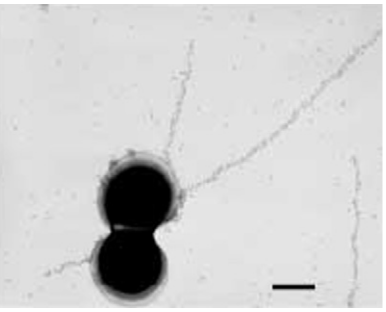

**FIGURE 12–1** Immunogold labeling and transmission electron microscopy of group B streptococcal organisms showing long pilus-like structures extending from the cell surface. *(From Lauer P, et al. Genome analysis reveals pili in group B streptococcus. Science 309:105, 2005.)*

## ULTRASTRUCTURE

Early concepts suggested a thick, rigid peptidoglycan layer external to the cytoplasmic membrane surrounded by concentric layers of cell wall antigens. The group-specific carbohydrate was thought to be "covered" by a type-specific CPS. Evidence now supports a model in which the group B carbohydrate and the CPS are linked independently to cell wall peptidoglycan [48].

Immunoelectron techniques reveal abundant CPS on Lancefield prototype strains Ia, II, and III, whereas less dense capsules are found on type Ib strains (Fig. 12–2) [49]. Similarly, incubation of the reference strains with homologous type-specific antisera reveals a thick capsular layer on types IV, V, and VI [50,51]. Ultrastructural studies show that the C protein also has a surface location [49]. CPS capsule expression can be regulated by altering cell growth rate [52]. Immunogold labeling and transmission electron microscopy show that the GBS pilus-like structures extend from the bacterial surface [9].

## IMMUNOCHEMISTRY OF POLYSACCHARIDE ANTIGENS

Although Lancefield's initial serologic definition was achieved by extraction methods that employed 2N hydrochloric acid and heat treatment, these procedures resulted in degraded antigens of small molecular mass. When more gentle techniques were employed for extraction, large molecular mass or "native" polysaccharides were isolated that contained an additional antigenic determinant, *N*-acetylneuraminic acid or sialic acid. Human immunity has been shown to correlate with antibody to the sialic acid–containing type III structure [53]. The composition of the group B polysaccharide initially was determined using antigen extracted from whole cells of the Lancefield laboratory–adapted variant strain 090R, devoid of CPS. With the use of contemporary methods for determination, L-rhamnose, D-galactose, 2-acetamido-2-deoxy-D-glucose, and D-glucitol have been identified as its constituent monosaccharides. It is composed of four different oligosaccharides, designated I though IV, and linked by one type of phosphodiester bond to form a complex, highly branched multiantennary structure [54].

The repeating unit structures of the group B streptococcal CPS, determined by methylation analysis combined with gas-liquid chromatography/mass spectrometry, are schematically represented in Figure 12–3. CPS of types Ia, Ib, and III have a five-sugar repeating unit containing galactose, glucose, *N*-acetylglucosamine, and sialic acid in a ratio of 2:1:1:1 [53,55–57]. The type II and type V polysaccharides have a seven-sugar repeating unit; type IV and type VII polysaccharides have six-sugar repeats, and type VIII polysaccharide has a four-sugar repeating unit [50,58–62]. The molar ratios vary, but the component monosaccharides are the same among the polysaccharide types except that type VI lacks *N*-acetylglucosamine and type VIII contains rhamnose in the backbone structure [63].

Each antigen has a backbone repeating unit of two (Ia, Ib), four (II), or three (III, IV, V, VII, VIII) monosaccharides to which one or two side chains are linked. Sialic acid is the exclusive terminal side chain sugar except for

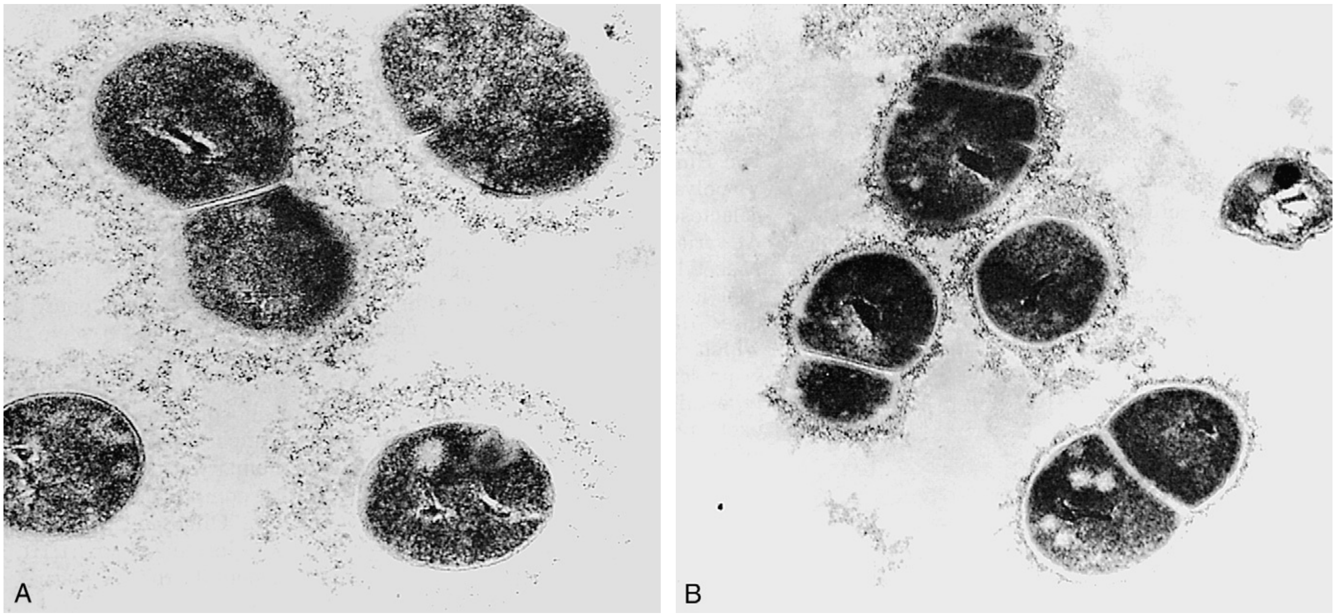

**FIGURE 12–2 Electron micrographs of thin sections of type Ia group B streptococcal prototype strains. A,** Strain 090. **B,** Strain A909. Both are stained with ferritin-conjugated type Ia–specific rabbit antibodies. The larger capsule is representative of those found also in Lancefield prototype II strain (18RS21) and type III isolates from infants with meningitis (M732), whereas the smaller capsule is representative of that also found on Lancefield prototype strain Ib (H36B). *(Micrographs courtesy of Dennis L. Kasper, MD.)*

the type II polysaccharide, which also has a terminal galactose. The structures of the type Ia and type Ib polysaccharides differ only in a single monosaccharide side chain linkage, although there are differences in the tertiary configuration of the molecules [64]. These monosaccharide linkages are critical to their immunologic specificity and explain their immunologic cross-reactivity [28,65]. The desialylated type III polysaccharide is immunologically identical to that of type 14 *Streptococcus pneumoniae* [66]. This observation stimulated investigations concerning the immunodeterminant specificity of human immunity to type III GBS and of antibody recognition of conformational epitopes as a facet of the host immune response [67,68]. The type III polysaccharide also can form extended helices. The position of the conformational epitope along these helices is potentially important to binding site interactions [69,70].

## GROWTH REQUIREMENTS AND BACTERIAL PRODUCTS

GBS are quite homogeneous in their amino acid requirements during aerobic or anaerobic growth [71]. A glucose-rich environment enhances the number of viable GBS during stationary phase and the amount of CPS elaborated [72]. In a modified chemically defined medium, the expression of capsule during continuous growth is regulated by the growth rate [52]. Group B streptococcal invasiveness is enhanced by a fast growth rate and is optimal in the presence of at least 5% oxygen [73,74].

GBS elaborate many products during their growth, some of which contribute to virulence of the organism. Among these is the hemolysin that produces the β-hemolysis surrounding group B colonies on blood agar plates. Hemolysin is an extracellular product of almost all strains and is active against the erythrocytes from several mammalian species. It has been isolated and characterized and is known to function as a virulence factor [75]. Hemolysin is not detected in supernatants of broth cultures, suggesting either that it exists in a cell-bound form, or that it is released by cells and rapidly inactivated.

After growth to stationary phase, GBS produce two types of pigment resembling a β-carotenoid [76]. Pigment, similar to hemolysin, is formed and released by an active metabolic process, retaining its properties only in the presence of a carrier molecule. A potential role for pigment as a virulence factor is proposed, but to date has not been proved.

GBS can hydrolyze hippuric acid to benzoic acid and glycine, and this property has been useful historically to distinguish GBS from other β-hemolytic groups [77]. Ferrieri and coworkers [78] isolated and characterized the hippuricase of GBS. This enzyme is cell associated and is trypsin and heat labile. It is antigenic in rabbits, but its relationship to bacterial virulence, if any, has not been studied.

Most strains of GBS have an enzyme that inactivates complement component C5a by cleaving a peptide at the carboxyl terminus [79]. Group B streptococcal C5a-ase seems to be a serine esterase; it is distinct from the C5a-cleaving enzyme (termed *streptococcal C5a peptidase*) produced by group A streptococci [80], although the genes that encode these enzymes are similar [81]. C5a-ase contributes to the pathogenesis of group B streptococcal disease by rapidly inactivating the neutrophil agonist C5a, preventing the accumulation of neutrophils at the site of infection [82].

Another group of enzymes elaborated by nearly all GBS are the extracellular nucleases [83]. Three distinct nucleases have been physically and immunologically characterized. All are maximally activated by divalent cations of calcium plus manganese. These nucleases are immunogenic in animals, and neutralizing antibodies to them are detectable in sera from pregnant women known to be

**FIGURE 12–3** Repeating unit structures of group B streptococcal capsular polysaccharides type Ia [64], type Ib [64,65], type II [60,62], type III [56,57], type IV [61], type V [58], type VI [730], type VII [59], and type VIII [63].

genital carriers of GBS. Their role in the pathogenesis of human infection is unknown.

An extracellular product that can contribute to virulence of GBS was originally defined as a neuraminidase and has been characterized more recently as a hyaluronate lyase [84]. Maximal levels are detected during late exponential growth in a chemically defined medium. Elaboration of large quantities can be a virulence factor for type III GBS. Musser and coworkers [85] identified a high neuraminidase–producing subset of type III strains that were responsible for most serious group B streptococcal infections. Later studies indicated that these were from a single clonal complex designated ST 17 that has been designated as "hypervirulent." ST 17 is almost exclusively found in type III strains.

GBS synthesize acylated (lipoteichoic) and deacylated glycerol teichoic acids that are cell associated and can be readily extracted and purified [86]. Strains from infants with early-onset or late-onset disease have higher levels of cell-associated and native deacylated lipoteichoic acid, and this product seems to contribute to attachment to human cells [87].

## EPIDEMIOLOGY AND TRANSMISSION

The relationship between GBS strains of human and bovine origin has been queried for years. There is no compelling evidence to suggest that cattle serve as a reservoir for human disease, and transmission of GBS from cows to humans is exceedingly rare [25]. In addition, during the past decades when group B *Streptococcus* has been a dominant human pathogen in the United States, most of the population has lacked exposure to the two possible modes of transmission: (1) proximity to dairy cattle (direct contact) and (2) ingestion of unpasteurized milk. Application of molecular techniques to type III strains from bovine sources and strains infecting human neonates supports the assertion that these lineages are unrelated. Phylogenetic lineage determination does indicate, however, that some clonal complexes of invasive or colonizing strains in humans are related to "ancestral" lineages of bovine GBS [88].

## ASYMPTOMATIC INFECTION (COLONIZATION) IN ADULTS

Group B streptococcal infection limited to mucous membrane sites is designated as asymptomatic infection, colonization, or carriage. Comparisons of the prevalence of colonization are related to differences in ascertainment techniques. Factors that influence the accuracy of colonization detection include density of colonization, choice of bacteriologic media, body sites sampled, number of culture specimens obtained, and time interval of study.

Isolation rates are higher with use of broth rather than solid agar media, with media containing substances inhibitory for normal flora (usually antimicrobials), and with selective broth rather than selective solid agar media. Among selective broth media, Todd-Hewitt broth with gentamicin (4 to 8 μg/mL) or colistin (or polymyxin B) (10 μg/mL) and nalidixic acid (15 μg/mL) (Lim broth), with or without sheep red blood cells, has been useful for accurate detection of GBS from genital and rectal cultures [89]. Such media inhibit the growth of most gram-negative enteric bacilli and other normal flora that make isolation of streptococci from these sites difficult. Use of broth media enables detection of low numbers of organisms that escape detection when inoculation of swabs is directly onto solid agar.

Isolation rates also are influenced by body sites selected for culture. Female genital culture isolation rates double with progression from the cervical os to the vulva [90,91]. In addition, culture sampling of lower genital tract and rectal sites increases group B streptococcal colonization rates 10% to 15% beyond that found if a single site is cultured [92]. The urinary tract is an important site of group B streptococcal infection, especially during pregnancy, when infection is typically manifested as asymptomatic bacteriuria. To predict accurately the likelihood of neonatal exposure to GBS at delivery, maternal culture specimens from the lower vagina and rectum (not perianal area) should be collected.

In neonates, external auditory canal cultures are more likely to yield GBS than cultures from anterior nares, throat, umbilicus, or rectum in first 24 hours of life [3,93], and isolation of organisms from the ear canal is a surrogate for the degree of contamination from amniotic fluid and vaginal secretions sequestered during the birth process. After the first 48 hours of life, throat and rectal sites are the best sources for detection of GBS, and positive cultures indicate true colonization (multiplication of organisms at mucous membrane sites), not just maternal exposure [94]. Cultures from the throat and rectum are the best sites for detection during childhood and until the start of sexual activity, when the genitourinary tract becomes a common site of colonization [95,96].

The prevalence of group B streptococcal colonization is influenced by the number of cultures obtained from a site and the interval of sampling. Historically, longitudinal assessment during pregnancy defined vaginal colonization patterns as chronic, transient, intermittent, or indeterminant [97]. A longitudinal cohort study of nonpregnant young women in the 1970s found that among women who were culture-negative at enrollment, almost half acquired vaginal colonization during follow-up at three 4-month intervals [98]. The duration of any group B streptococcal colonization among college students was estimated by Foxman and colleagues [99] and is longer for women (14 weeks) than for men (9 weeks). Nearly half of women vaginally colonized at delivery have had negative antenatal culture results. In a more recent longitudinal study of pregnant women, the predictive value of a positive prenatal vaginal or rectal culture from the second trimester for colonization at delivery was 67% [100]. The predictive value of a positive prenatal culture result is highest (73%) in women with vaginal and rectal colonization and lowest (60%) in women with rectal colonization only. Cultures performed 1 to 5 weeks before delivery are fairly accurate in predicting group B streptococcal colonization status at delivery in term parturients. Within this interval, the positive predictive value is 87% (95% confidence interval 83 to 92), and the negative predictive value is 96% (95% confidence interval 95 to 98). Culture specimens collected within this interval perform significantly better than specimens collected 6 or more weeks before delivery [101].

The primary reservoir for GBS is the lower gastrointestinal tract [3,102]. The recovery of GBS from the rectum alone is three to five times more common than recovery from the vagina [92], the rectal-to-vaginal isolation ratio exceeds 1 [100], and the rectal site more accurately predicts persistence [92] or chronicity of carriage [103]. Fecal carriage or rectal colonization with GBS has been documented in individuals ranging in age from 1 day to 80 years [104]. Additional support for the intestine as the primary reservoir of colonization by GBS includes their isolation from the small intestine of adults [105] and their association with infections resulting from surgery of the upper or lower intestinal tract [106]. Rectal colonization also can contribute to the resistance of genital tract colonization to temporary decolonization by antibiotics [107].

Several factors influence genital carriage of GBS. Among healthy young men and women living in a college dormitory, sexually experienced subjects had twice the colonization rates of sexually inexperienced subjects [108]. In a longitudinal cohort study of nonpregnant young women, African American ethnicity, having multiple sex partners during a preceding 4-month interval, having frequent sexual intercourse within the same interval, and having sexual intercourse within the 5 days before a follow-up visit were independently associated with vaginal acquisition of GBS [98]. These findings suggest either that the organism is sexually transmitted or that sexual activity alters the microenvironment to make it more permissive to colonization. In another study of college women, GBS were isolated significantly more often from sexually experienced women, women studied during the first half of the menstrual cycle, women with an intrauterine device, and women 20 years old or younger [109]. Colonization with GBS also occurs at a high rate in healthy college students and is associated with having engaged in sexual activity, tampon use, milk consumption, and hand washing done four times daily or less [110]. Fish consumption increased the risk of acquiring some, but not all, capsular types [111].

A higher prevalence of colonization with GBS has been found among pregnant diabetic patients than among nondiabetic controls [112]. Carriage over a prolonged interval reportedly occurs more often in women who use tampons than women who do not [113]. Colonization is more frequent among teenage women than among women 20 years of age or older [97,109,114] and among women with three or fewer pregnancies than in women with more than three pregnancies [97,114,115]. Genital isolation rates are significantly greater in patients attending sexually transmitted disease clinics than in patients attending other outpatient facilities [90,116]. Ethnicity is related to colonization rates. In one large multicenter U.S. pregnancy study, colonization rates were highest in Hispanic women of Caribbean origin, followed by African Americans, whites, and other Hispanics [115]. In other assessments of geographically and ethnically diverse populations, the rate of colonization at delivery was significantly higher among African American women than in other racial or ethnic groups [98,117,118]. A large inoculum of vaginal group B streptococcal colonization also was more common among African American than among Hispanic or non-Hispanic white women [119]. Factors that do *not* influence the prevalence of genital colonization in nonpregnant women include use of oral contraceptives [109]; marital status; presence of vaginal discharge or other gynecologic signs or symptoms [109]; carriage of *Chlamydia trachomatis*, *Ureaplasma urealyticum*, *Trichomonas vaginalis*, or *Mycoplasma hominis* [115]; and infection with *Neisseria gonorrhoeae* [90,91].

Colonization with GBS can elicit an immune response. In a group of pregnant women evaluated at the time of admission for delivery, vaginal or rectal colonization with serotype Ia, II, III, or V was associated with significantly higher serum concentrations of IgG specific for the colonizing CPS type compared with noncolonized women [117]. Moderate concentrations of Ia, Ib, II, III, and V CPS-specific IgG also were found in association with colonization during pregnancy [120]. Maternal colonization with type III was least likely to be associated with these CPS-specific antibodies. In contrast to infection with organisms such as *N. gonorrhoeae* or genital mycoplasmas, genital infection with GBS is not related to genital symptoms [109,116,121].

GBS have been isolated from vaginal or rectal sites or both in 15% to 40% of pregnant women. These variations in colonization rates relate to intrinsic differences in populations (age, ethnicity, parity, socioeconomic status, geographic location) and to lack of standardization in culture methods employed for ascertainment. True population differences account for some of the disparity in these reported prevalence rates. When selective broth media are used, and vaginal and rectal samples are cultured, the overall prevalence of maternal colonization with GBS by region is 12% in India and Pakistan, 19% in Asia and the Pacific Islands, 19% in sub-Saharan Africa, 22% in the Middle East and North Africa, 14% in Central and South America, and 26% in the United States [117,122]. The reported rates of colonization among pregnant women range from 20% to 29% in eastern Europe, 11% to 21% in western Europe, 21% to 36% in Scandinavia, and 7% to 32% in the southern part of Europe [123]. The rate of persistence of group B streptococcal colonization in a subsequent pregnancy is higher compared with women negative for colonization in their prior pregnancy [124]. The prevalence rates of pharyngeal colonization among pregnant and nonpregnant women and heterosexual men are similar [3,125,126]; however, the rate approaches nearly 20% in men who have sex with men [127]. No definite relationship between isolation of GBS from throat cultures of adults or children and symptoms of pharyngitis has been proved [128], but some investigators have suggested that these organisms can cause acute pharyngitis [126].

## ASYMPTOMATIC INFECTION IN INFANTS AND CHILDREN

Sites of colonization with GBS differ in children versus adults. In a study of 100 girls ranging in age from 2 months to 16 years, Hammerschlag and coworkers [95] isolated GBS from lower vaginal, rectal, or pharyngeal sites, or all three, in 20% of children. The prevalence of positive pharyngeal cultures resembled the prevalence of adults in girls 11 years or older (5%), but approached

the prevalence reported for neonates in younger girls (15%). Rectal colonization was detected frequently in girls younger than 3 or older than 10 years of age (about 25%), but was uncommon in girls 3 to 10 years of age. Mauer and colleagues [96] isolated GBS from cultures of vaginal, anal, or pharyngeal specimens or all three in 11% of prepubertal boys and girls. Pharyngeal (5% each) and rectal (10% and 7%) isolation rates were similar for boys and for girls. Persson and coworkers [129] detected fecal group B streptococcal carriage in only 4% of healthy boys and girls, and Cummings and Ross [130] found that only 2% of English schoolchildren had pharyngeal carriage. Taken together, these findings indicate that the gastrointestinal tract is a frequent site for carriage during infancy and childhood in boys and girls, and genital colonization in girls is uncommon before puberty [131]. Whether this relates to environmental influences in the prepubertal vagina or to lack of sexual experience before puberty, or both, awaits further study.

## TRANSMISSION OF GROUP B STREPTOCOCCI TO NEONATES

The presence of GBS in the maternal genital tract at delivery is the significant determinant of colonization and infection in the neonate. Exposure of the neonate to the organism occurs by the ascending route in utero through translocation through intact membranes, through ruptured membranes, or by contamination during passage via the birth canal. Prospective studies have indicated vertical transmission rates of 29% to 85%, with a mean rate of approximately 50% among neonates born to women from whom GBS were isolated from cultures of vagina or rectum or both at delivery. Conversely, only about 5% of infants delivered to culture-negative women become asymptomatically colonized at one or more sites during the first 48 hours of life.

The risk of a neonate acquiring colonization by the vertical route correlates directly with the density of colonization (inoculum size). Neonates born to heavily colonized women are more likely to acquire carriage at mucous membrane sites than neonates born to women with low colony counts of GBS in vaginal cultures at delivery [132]. Boyer and associates [100] found that rates of vertical transmission were substantially higher in women with heavy than in women with light colonization (65% versus 17%) and that colonization at multiple sites and development of early-onset disease were more likely among infants born to heavily colonized mothers. The likelihood of colonization in a neonate born to a woman who is culture-positive at delivery is unrelated to maternal age, race, parity, or blood type or to duration of labor or method of delivery [100]. It is unclear whether preterm or low birth weight neonates are at higher risk for colonization from maternal sources than term infants.

Most neonates exposed through their mothers to GBS have infection that is limited to surface or mucous membrane sites (colonization) that results from contamination of the oropharynx, gastric contents, or gastrointestinal tract by swallowing of infected amniotic fluid or maternal vaginal secretions. Healthy infants colonized from a maternal source show persistence of infection at mucous membrane sites for weeks [133,134]. The distribution of CPS types in group B streptococcal isolates from mothers is comparable to that in isolates from healthy neonates.

Other sources for group B streptococcal colonization in neonates have been established. Horizontal transmission from hospital or community sources to neonates is an important, albeit less frequently proved, mode for transmission of infection [105,134]. Cross-contamination from maternally infected to uninfected neonates can occur from hands of nursery personnel [135]. In contrast to group A streptococci, which can produce epidemic disease in nurseries, GBS rarely exhibit this potential, and isolation of neonates with a positive culture result from skin, umbilical, throat, or gastric cultures is never indicated. An epidemic cluster of five infants with late-onset bacteremic infection related to type Ib GBS occurred among very low birth weight infants in a neonatal intensive care unit in the 1980s [136]. None of the index cases was colonized at birth, establishing that acquisition during hospitalization had occurred. Phage typing identified two overlapping patterns of susceptibility believed to represent a single epidemic strain. Epidemiologic analysis suggested infant-to-infant spread by means of the hands of personnel, although acquisition from two nurses colonized with the same phage–type Ib strain was not excluded. The infection control measures instituted prevented additional cases. This and other reports [135,137] indicate that cohorting of culture-positive infants during an outbreak coupled with implementation of strict hand hygiene for infant contact significantly diminishes nosocomial acquisition.

Community sources afford potential for transmission of GBS to the neonate. Indirect evidence has suggested that this mode of infection is infrequent [134]. Only 2 of 46 neonates culture-negative for GBS when discharged from the newborn nursery acquired mucous membrane infection at 2 months of age [138]. The mode of transmission likely is fecal-oral. Whether acquired by vertical or horizontal mode, colonization of mucous membrane sites in neonates and young infants usually persists for weeks or months [139].

## SEROTYPE DISTRIBUTION OF ISOLATES

The differentiation of GBS into types based on CPS antigens has provided a valuable tool in defining the epidemiology of human infection. In the 1970s and 1980s, virtually all evaluations of GBS isolated from healthy neonates, children, or adults revealed an even distribution into types Ia or Ib, II, and III. This distribution also was reported for isolates from neonates with early-onset infection without meningitis and their mothers [140,141]. In 1990, types other than I, II, or III accounted for less than 5% of all isolates.

Beginning in the early 1990s, reports from diverse geographic regions documented type V as a frequent cause of colonization and invasive disease, first in neonates and later in adults [142–144]. The emergence of type V is not due to a single clone, but most type V isolates do have one pulse-field gel electrophoresis pattern that has been present in the United States since 1975 [145]. Type V now causes a substantial proportion of cases of early-

onset disease and of infection among pregnant women. Type Ia has increased in prevalence and a corresponding decline has occurred in type II strains causing perinatal disease [143]. Type III strains, which account for about 70% of isolates from infants with meningitis, continue to be isolated from about two thirds of infants with late-onset disease [146,147]. Types VI, VII, VIII, and IX rarely cause human disease in the United States or the United Kingdom, but types VI and VIII are the most common serotypes isolated from healthy Japanese women [148,149].

The contemporary CPS type distribution of GBS from different patient groups is shown in Figure 12–4. Prospective population-based surveillance through the Active Bacterial Core Surveillance/Emerging Infections Program Network of the U.S. Centers for Disease Control and Prevention (CDC) defined the epidemiology of invasive group B streptococcal disease in the United States from 1999-2005 [150]. Serotyping was performed for greater than 6000 isolates. Among these, the group B streptococcal types represented in 528 early-onset disease cases were Ia (30%), III (28%), V (18%), and II (13%). The distribution for 172 pregnancy-associated cases was similar. The type distribution among 469 late-onset cases was Ia (24%), III (51%), and V (14%). Type V predominated among almost 5000 cases in nonpregnant adults, accounting for 31% of cases, followed by Ia (24%), II (12%), and III (12%).

## MOLECULAR EPIDEMIOLOGY

In the 1970s and 1980s, epidemiologic investigation of group B streptococcal infections was hampered initially by the lack of a discriminatory typing system. Initial investigations employed phage typing in combination with serologic classification to discriminate between infant acquisition of GBS from maternal or nosocomial sources [151]. Although plasmids have been described in a few GBS [152], their use as epidemiologic markers is complex.

Tools such as multilocus enzyme electrophoresis [85,153,154], restriction enzyme fragment length polymorphism analysis, pulsed-field gel electrophoresis [155], and a random-amplified polymorphic DNA assay [156] have been employed for molecular characterization of group B streptococcal isolates associated with human disease. Restriction enzyme fragment length polymorphism analysis no longer is used because there are allelic variations within some CPS types. These techniques have indicated that some geographically and epidemiologically distinct isolates have identical patterns [157], suggesting dissemination of a limited number of clones in the United States; have shown the molecular relatedness of mother-infant and twin-twin strains [148,156]; and have documented mother-to-infant transmission associated with ingestion of infected mother's milk [157]. Molecular typing techniques have confirmed that sexual partners often carry identical strains. Multilocus sequence typing and capsular gene cluster (*cps*) genotyping has been used to investigate the dynamics of perinatal colonization. Changes in capsule expression and recolonization with antigenically distinct group B streptococcal clones were detected in culture-positive women over time by applying multilocus sequence typing [158].

Molecular characterization has been employed to explore the role of virulence clones in contributing to invasive disease. Type III GBS were classified into three major phylogenetic lineages on the basis of bacterial DNA restriction digest patterns [159]. Most cases of type III neonatal invasive disease seem to be caused by strains with the restriction digest pattern type III-3. The genetic variation that distinguishes restriction digest pattern type III-3 strains seems to occur within localized areas of the genome that contain known or putative virulence genes [160–162]. Using genomic subtractive hybridization to identify regions of the genome unique to virulent restriction digest pattern type III-3 strains, a surface protein was identified that mediates epithelial cell invasion [163]. Using multilocus sequence typing, 10 allelic profiles were identified among type III isolates recovered from neonates with invasive disease and from colonized pregnant women [164]. The allelic profiles converged into three groups on concatenation. There was an equal distribution of these groups among colonizing and invasive isolates.

The finding that isolates with different capsular serotypes have the same sequence type suggests that capsular switching can occur [164,165]. One pulsed-field gel electrophoresis group bearing a gene from the capsular synthesis operon has been shown in type III strains causing neonatal meningitis, but not in type III colonizing strains [166]. Clustering of most invasive neonatal isolates into major pulsed-field gel electrophoresis groups has been noted [167]. Also, among type III strains evaluated by multilocus sequence typing, a single clone, ST 17, also called clonal complex 1 by other investigators, has been reported to be "hypervirulent," but this is controversial. Additional studies are required to elucidate the differences in virulence among clones identified by these techniques [168].

## INCIDENCE OF INFECTION IN NEONATES AND PARTURIENTS

Two clinical syndromes occur among young infants with group B streptococcal disease that are epidemiologically distinct and relate to age at onset [2,3]. Historically, the attack rates for the first of these syndromes, designated early-onset because it occurs within the first 6 days of life (mean onset 12 to 18 hours), ranged from 0.7 to 3.7 per 1000 live births. The attack rates for late-onset infection (mean onset 7 to 89 days of age) ranged from 0.5 to 1.8 per 1000 live births. Multistate active surveillance that identified cases of invasive disease in a population of 10.1 million in 1990 reported an incidence of 1.6 and 0.3 per 1000 live births for early-onset and late-onset disease [169]. Incidence of disease was significantly higher among African Americans than among whites. The crude incidence was higher among Hispanic whites than among non-Hispanic whites. These multistate surveillance findings are in accord with findings from a cohort study conducted in Atlanta indicating a higher risk for early-onset or late-onset disease among African American infants than among infants of other ethnic origins [170].

There has been a dramatic decline in the incidence of early-onset disease in the United States in association with implementation of universal antenatal culture screening and use of IAP. From 1993-1998, when risk-based and culture-based methods were in use, incidence of early-onset disease declined by 65%, from 1.7 to 0.6 per 1000 live births [12]. Comparison of the two approaches showed the superiority of the culture-based approach [171]. The incidence of early-onset disease has declined an additional 27% in association with implementation in 2002 of revised consensus guidelines advocating a culture-based approach for prevention of early-onset disease to a rate of 0.34 per 1000 live births in 2007 [150]. The burden of early-onset disease initially was disproportionately high in African American infants for reasons that were not well defined and then decreased in 2003-2005, but more recent data indicate reemergence of this disparity. Factors that might contribute to the disparity include higher maternal colonization rates and higher rates of preterm deliveries in African American women compared with white women, but additional study is needed [172]. In contrast to its impact on early-onset disease, use of IAP has had *no* impact on the incidence of late-onset disease, which has remained stable at 0.3 to 0.4 per 1000 live births since 2002 [150].

The male-to-female ratio for early-onset and late-onset group B streptococcal disease is equal at 1:1. Before 1996, 20% to 25% of all infants with group B streptococcal disease had onset after the first 6 days of life. In 2008, approximately 50% of all infants had disease with onset after 6 days of life [173]. Infants born prematurely

constituted 23% of the total with early-onset disease and 52% of the total with late-onset disease.

The importance of group B *Streptococcus* as a common pathogen for the perinatal period relates to the pregnant woman as well as her infant. Postpartum endometritis occurs with a frequency of approximately 2%, and clinically diagnosed intra-amniotic infection occurs in 2.9% of women vaginally colonized with GBS at the time of delivery. The risk of intra-amniotic infection is greater in women with heavy colonization [174]. Implementation of intrapartum chemoprophylaxis has been associated with a significant decline in the incidence of invasive disease in pregnant women, from 0.29 per 1000 live births in 1993 to 0.23 per 1000 live births in 1998 and a further decline to 0.12 per 1000 live births in 1999-2005 [150,171]. Half of these infections were associated with infection of the upper genital tract, placenta, or amniotic sac and resulted in fetal death. Among the other infections, bacteremia without a focus (31%), endometritis without fetal death (8%), and chorioamnionitis without fetal death (4%) were the most common manifestations.

# IMMUNOLOGY AND PATHOGENESIS

## HOST-BACTERIAL INTERACTIONS RELATED TO PATHOGENESIS

The prevalence and severity of group B streptococcal diseases in neonates have stimulated intensive investigation to elucidate the pathogenesis of infection. The unique epidemiologic and clinical features of group B streptococcal disease pose several basic questions that provide a framework for hypothesis development and experimental testing: How does the organism colonize pregnant women and gain access to the infant before or during delivery? Why are newborns, especially infants born prematurely, uniquely susceptible to infection? What allows GBS to evade host innate immune defenses? How do these organisms gain entry to the bloodstream and then cross the blood-brain barrier to produce meningitis? What specific GBS factors injure host tissues or induce the sepsis syndrome?

Advances in knowledge of pathogenesis have been achieved through development of cell culture systems and animal models. Refinement of molecular genetic techniques has yielded isogenic mutant strains varying solely in the production of a particular component (e.g., CPS). Such mutants are important in establishing the biologic relevance of a given trait and its requirement for virulence in vivo. The sequencing of several complete GBS genomes has provided additional context for interpretation of experimental data and comparison with other well-studied pathogens [7,8].

Although GBS have adapted well to asymptomatic colonization of healthy adults, they remain a potentially devastating pathogen to susceptible infants. This section reviews the current understanding of virulence mechanisms, many of which are revealed or magnified by the unique circumstances of the birth process and the deficiencies of neonatal immune defense. The group B streptococcal virulence factors defined to date, with mode of action and proposed role in pathogenesis, are shown in Table 12–1. Key stages in the molecular, cellular, and immunologic pathogenesis of newborn infection are summarized schematically in Figure 12–5.

### Maternal Colonization

The presence of GBS in the genital tract of the mother at delivery determines whether or not a newborn is at risk for invasive disease. Among infants born to colonized women, the risk of early-onset disease is approximately 30-fold that for infants born to women with a negative result on prenatal cultures [175]. A direct relationship exists between the degree (inoculum size) of group B streptococcal vaginal colonization, the risk of vertical transmission, and the likelihood of serious disease in the newborn [132,176]. Consequently, a crucial step in the pathogenesis of invasive disease in the newborn caused by GBS is colonization of pregnant women.

To establish colonization of the female genital tract, GBS must adhere successfully to the vaginal epithelium. Compared with other microorganisms, GBS bind very efficiently to exfoliated human vaginal cells or vaginal tissue culture cells [177,178], with maximal adherence at the acidic pH characteristic of vaginal mucosa [179,180]. A low-affinity interaction with epithelial cells is mediated by its amphiphilic cell wall–associated lipoteichoic acid, whereas higher affinity interactions with host cells are mediated by hydrophobic surface proteins. Soluble lipoteichoic acid competitively inhibits epithelial cell adherence [181,182] and decreases vaginal colonization of pregnant mice [183].

High-affinity protein-mediated interactions of GBS with epithelium are mediated largely through extracellular matrix components, such as fibronectin, fibrinogen, and laminin, which interact with host cell–anchored proteins such as integrins. Binding occurs to immobilized, but not soluble fibronectin, suggesting that this interaction requires close proximity of multiple fibronectin molecules and group B streptococcal adhesins [184]. More recently, a genome-wide phage display technique revealed a fibronectin-binding property associated with the surface-anchored group B streptococcal C5a peptidase, ScpB [185]. The dual functionality of ScpB was confirmed by decreased fibronectin binding of isogenic ScpB mutants and the direct interaction of recombinant ScpB with solid-phase fibronectin [185,186]. Similar targeted mutagenesis studies showed that adherence of GBS to laminin involves a protein adhesin called Lmb [187], attachment to fibrinogen is mediated by repetitive motifs within the surface-anchored protein FbsA [188], and binding to human keratin 4 is carried out by the serine-rich repeat domain protein Srr-1 [189].

More recently, GBS were revealed to express filamentous cell surface appendages known as pili [9]. Among eight sequenced GBS genomes, two genetic loci encoding pili were identified, although not all genomes contain both loci [190]. One of these islands includes genes encoding PilB, an LP(x)TG motif–containing protein that polymerizes to form a pilus backbone, along with accessory pilus proteins PilA and PilC [47,191]. Epithelial cell adherence was reduced in isogenic GBS mutants lacking PilA or PilC, but not mutants lacking the PilB backbone [191].

**TABLE 12–1** Group B Streptococcal Virulence Factors in Pathogenesis of Neonatal Infection

| Virulence Factor | Molecular or Cellular Actions | Proposed Role in Pathogenesis |
|---|---|---|
| ***Host Cell Attachment and Invasion*** | | |
| C surface protein | Binds cervical epithelial cells | Epithelial cell adherence, invasion |
| Fibrinogen receptor, FbsA | Binds fibrinogen in extracellular matrix | Epithelial cell attachment |
| Lipoteichoic acid | Binds host cell surfaces | Epithelial cell attachment |
| C5a peptidase, ScpB | Binds fibronectin in extracellular matrix | Epithelial cell adherence, invasion |
| Surface protein Lmb | Binds laminin in extracellular matrix | Epithelial cell attachment |
| Spb1 surface protein | Promotes epithelial cell uptake | Invasion of epithelial barriers |
| *iagA* gene | Alteration in bacterial cell surface (?) | Promotes blood-brain barrier invasion |
| ***Injury to Host Tissues*** | | |
| β-Hemolysin/cytolysin | Lyses epithelial and endothelial cells | Damage and spread through tissues |
| Hyaluronate lyase | Cleaves hyaluronan or chondroitin sulfate | Promotes spread through host tissues |
| CAMP factor | Lyses host cells (cohemolysin) | Direct tissue injury |
| ***Resistance to Immune Clearance*** | | |
| Exopolysaccharide capsule | Impairs complement C3 deposition and activation | Blocks opsonophagocytic clearance |
| C5a peptidase, ScpB | Cleaves and inactivates human C5a | Inhibits neutrophil recruitment |
| CAMP factor | Binds to Fc portion of IgG, IgM | Impairment of antibody function |
| Serine protease, CspA | Cleaves fibrinogen, coats GBS surface with fibrin | Blocks opsonophagocytosis |
| Fibrinogen receptor, FbsA | Steric interference with complement function (?) | Blocks opsonophagocytosis |
| C protein | Nonimmune binding of IgA | Blocks opsonophagocytosis |
| β-hemolysin/cytolysin | Lyses neutrophils and macrophages, proapoptotic | Impairment of phagocyte killing |
| Superoxide dismutase | Inactivates superoxide | Impairment of oxidative burst killing |
| Carotenoid pigment | Antioxidant effect blocks $H_2O_2$, singlet oxygen | Impairment of oxidative burst killing |
| *Dlt* operon genes | Alanylation of lipoteichoic acid | Interferes with antimicrobial peptides |
| Penicillin-binding protein 1a | Alteration in cell wall composition | Interferes with antimicrobial peptides |
| ***Activation of Inflammatory Mediators*** | | |
| Cell wall lipoteichoic acid | Binds host pattern recognition receptors (TLRs) | Cytokine activation |
| Cell wall peptidoglycan | Binds host pattern recognition receptors (TLRs) | Cytokine activation |
| β-Hemolysin/cytolysin | Activation of host cell stress response pathways | Triggers iNOS, cytokine release |

*GBS, group B streptococci; iNOS, inducible nitric oxide synthase; TLRs, toll-like receptors.*

Solution of the crystal structure of PilC reveals a specific IgG-like fold domain (N2) required for epithelial cell binding [192].

## Ascending Amniotic Infection

GBS can reach the fetus in utero through ascending infection of the placental membranes and amniotic fluid. Alternatively, the newborn may become contaminated with the organism on passage through the birth canal. Infection by the ascending route plays a pivotal role in early-onset disease. A direct relationship exists between the duration of membrane rupture before delivery and attack rate for early-onset disease [193], whereas an inverse relationship exists between the duration of membrane rupture and the age at which clinical signs of early-onset pneumonia and sepsis first appear [194]. When the duration of membrane rupture was 18 hours or less, the attack rate was 0.7 per 1000 live births; when it was more than 30 hours, the attack rate increased to 18.3 per 1000 [193]. Histologic examination of placentas from women with group B streptococcal chorioamnionitis showed bacterial infiltration along a choriodecidual course, implying that ascending infection may be a primary trigger in many instances of premature rupture [195].

GBS may promote membrane rupture and premature delivery by several mechanisms. Isolated chorioamniotic membranes exposed to the organism have decreased tensile strength and elasticity and are prone to rupture [196]. The presence of GBS at the cervix activates the maternal decidua cell peroxidase–hydrogen peroxide–halide system, promoting oxidative damage to adjacent fetal membranes [197]. GBS also can modify the arachidonic acid metabolism of cultured human amnion cells, favoring production of prostaglandin $E_2$ [198,199], which is known to stimulate the onset of labor. Stimulation of chorionic cell release of macrophage inflammatory protein-1α and interleukin (IL)-8 from human chorion cells recruits inflammatory cells that may contribute to infection-associated preterm labor [200].

GBS occasionally seem to penetrate into the amniotic cavity through intact membranes. Clinically, this mechanism of entry is suggested by anecdotal reports of

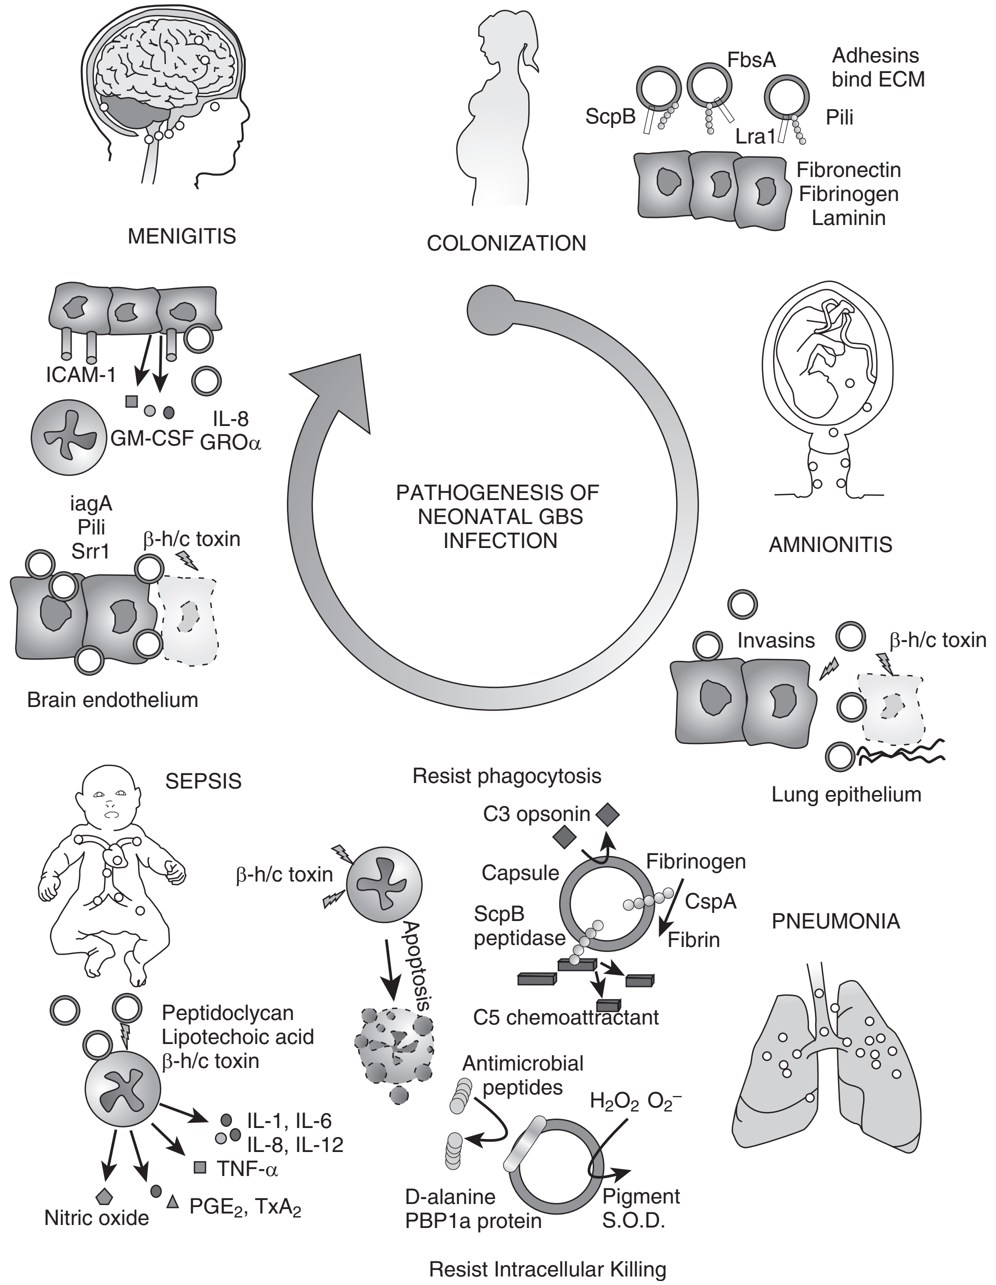

**FIGURE 12–5** Pathologic mechanisms for different types of neonatal group B streptococcal (GBS) infection. ECM, extracellular matrix; GM-CSF, granulocyte-macrophage colony-stimulating factor; ICAM, intercellular adhesion molecule; IL-8, interleukin-8; $PGE_2$, prostaglandin $E_2$; SOD, superoxide dismutase; TNF-α, tumor necrosis factor-α; $TxA_2$, thromboxane $A_2$. *(Adapted from Doran KS, Nizet V. Molecular pathogenesis of neonatal group B streptococcal infection: no longer in its infancy. Mol Microbiol 54:23-31, 2004.)*

neonates with fulminant early-onset infection after delivery by cesarean section and no identifiable obstetric risk factors [133,201,202]. Migration of the organism through freshly isolated chorioamniotic membranes has been documented by scanning and transmission electron microscopy [203]. GBS invade primary chorion cells efficiently in vitro and are capable of transcytosing through intact chorion cell monolayers without disruption of intracellular junctions [204]. They also secrete an enzyme that degrades hyaluronic acid, an important component of the extracellular matrix that is abundant in placental tissues and may facilitate amniotic invasion [84,205].

Amniotic fluid supports the proliferation of GBS [206], such that when the organism gains access to the uterine cavity a large inoculum can be delivered to the fetal lung; this results in a continuum of intrapartum (stillbirth) to early postpartum infant death [176,207–211]. In utero infection probably accounts for the 40% to 60% of newborns with early-onset disease who have poor Apgar scores and in whom pulmonary signs develop within a few hours of birth because these infants almost invariably

display clinical or histologic evidence of congenital pneumonia [193,208]. Conversely, when GBS are encountered in the immediate peripartum period or on passage through the birth canal, a lesser inoculum is delivered to the neonate. Although a small but meaningful risk of subsequent invasive disease exists, most of these newborns have asymptomatic colonization limited to mucosal surfaces and remain healthy.

## Pulmonary and Bloodstream Entry

Early-onset group B streptococcal disease is heralded by respiratory symptoms, including tachypnea, hypoxia, cyanosis, and pulmonary hypertension [212]. One third to more than half of infants are symptomatic at birth or within 4 to 6 hours after delivery. Autopsies in fatal early-onset cases reveal that 80% have histologic evidence of lobar or multilobar pneumonia [211,213], characterized by dense bacterial infiltration, epithelial cell damage, alveolar hemorrhage, interstitial inflammatory exudate, and hyaline membrane formation [210,214]. When pneumonia develops in newborn primates exposed by intra-amniotic injection of GBS, bacterial density reaches $10^9$ to $10^{11}$ organisms per gram of lung tissue [215]. As shown in rabbits, the poorer resolution of pneumonia in preterm versus term newborns reflects quantitative deficiency of pulmonary alveolar macrophages, mandating the recruitment of neutrophils as a secondary phagocytic defense mechanism [216].

Group B streptococcal disease rarely is limited to the initial pulmonary focus, but spreads to the bloodstream and is circulated through other organs and tissues. The capacity of GBS to cause disruption of the lung epithelial and endothelial barrier evidently involves the process of intracellular invasion, direct cytolytic injury, and damage induced by the inflammatory response of the newborn host. Intracellular invasion of alveolar epithelial and pulmonary endothelial cells by GBS was first noted in newborn macaques after intra-amniotic challenge [215] and later confirmed in human tissue culture lines derived from both cellular barriers [217,218]. In vivo and in vitro electron microscopy studies show that host cytoskeletal changes are triggered that lead to endocytotic uptake of the bacterium within a membrane-bound vacuole. Uptake requires induction of signal transduction pathways in the host cell that are mediated by Rho-family GTPases [219] and phosphatidylinositol-3 kinase [220].

Cellular invasion is correlated with virulence potential. Clinical isolates of GBS from infants with bloodstream infections invade epithelial cells better than strains from the vaginal mucosa of asymptomatic women [221]. FbsA, a group B streptococcal fibrinogen binding protein [222]; Lmb, which mediates laminin binding [223]; and ScpB, which interacts with fibronectin [186], each play a role in promoting efficient epithelial or endothelial cell invasion. Another GBS surface protein, Spb1, was identified by subtractive hybridization to play a specific role in serotype III GBS invasion of epithelial cells [163]. In addition, surface-anchored α C protein specifically interacts with host cell glycosaminoglycan on the epithelial cell surface to promote group B streptococcal internalization [224]. By contrast, CPS decreases intracellular invasion, presumably through steric interference of certain receptor-ligand interactions [225].

Although cellular invasion may play a principal role in bloodstream penetration in late-onset group B streptococcal infection, damage to the lung barrier often is evident in severe early-onset infection. Alveolar exudate and hemorrhage in autopsy studies of infants with group B streptococcal pneumonia attest to significant pulmonary epithelial and endothelial cell injury [210,226]. The cellular damage seems to result largely from the actions of β-hemolysin/cytolysin. This toxin is responsible for the characteristic β-hemolytic phenotype displayed by the organism when grown on sheep's blood agar. Mutagenesis and heterologous expression studies have identified a single open reading frame, *cylE*, as necessary for group B streptococcal β-hemolysin/cytolysin expression and sufficient to confer β-hemolysis when cloned in *Escherichia coli* [227,228]. CylE is a predicted 79-kDa protein sharing no homology to the toxin, streptolysin S, that is responsible for β-hemolysis in group A, C, F, and G streptococci [229]. This pore-forming toxin lyses lung epithelial and endothelial cells and compromises their barrier function [230,231]. At subcytolytic doses, it promotes intracellular invasion and triggers the release of IL-8, the principal chemoattractant for human neutrophils [232]. Mutants lacking hemolysin expression are less virulent than the corresponding wild-type strains in mouse, rat, and rabbit models of group B streptococcal pneumonia [233–235].

The cytolytic, proinvasive, and proinflammatory effects of group B streptococcal β-hemolysin/cytolysin all are neutralized by dipalmitoyl phosphatidylcholine, the major phospholipid constituent of human lung surfactant [230,232]. This finding may partly explain the increased risk in premature, surfactant-deficient neonates for severe lung injury and invasive disease from group B streptococcal infection. Treatment with exogenous surfactant reduces histologic evidence of lung inflammation, improves lung compliance, and mitigates bacterial growth in preterm rabbits infected with GBS [236,237]. Clinical studies exploring the effect of surfactant administration on human infants with group B streptococcal sepsis also suggest a beneficial effect [238,239].

## Capsular Polysaccharide and Immune Resistance

On penetration of GBS into the lung tissue or bloodstream of the newborn infant, an immunologic response is recruited to clear the organism. Central to this response are host phagocytic cells including neutrophils and macrophages. Effective uptake and killing by these cells require opsonization of the bacterium by specific antibodies in the presence of complement [240–242]. Neonates are particularly prone to invasive disease because of their quantitative or qualitative deficiencies in phagocytic cell function, specific antibody, or classic and alternate complement pathways. In addition to these newborn host susceptibilities, GBS possess numerous virulence determinants that seek to thwart each of the key components of effective opsonophagocytic killing. Chief among these factors is the sialylated group B streptococcal polysaccharide capsule.

The serotype-specific epitopes of group B streptococcal CPS are created by different arrangements of four monosaccharides (glucose, galactose, *N*-acetylglucosamine, and sialic acid) into a unique repeating unit (see "Immunochemistry of Polysaccharide Antigens" earlier), but unfailingly these structures contain a terminal sialic acid bound to galactose in an $\alpha 2 \rightarrow 3$ linkage. The enzymatic machinery for capsule biosynthesis is encoded in the single long transcript of a 16-gene operon. More recent elegant experiments have shown that the heterologous expression of a single polymerase gene (*cpsH*) from this operon can cause a group B streptococcal type Ia strain to express type III capsule epitopes, and vice versa [243].

The conserved group B streptococcal terminal $\alpha 2 \rightarrow 3$ sialic acid capsular component is identical to a sugar epitope widely displayed on the surface of all mammalian cells [244]. The terminal $\alpha 2 \rightarrow 3$-linked sialic acid is overexpressed in humans, who in evolution have lost the genes to produce the alternative sialic acid, Neu5Gc. It is suggested that group B *Streptococcus* may be a particularly troublesome human pathogen because its sialylated capsule has undergone selection to resemble host "self" and avoid immune recognition. Compared with wild-type strains, isogenic capsule-deficient mutants of GBS elicit greater degrees of proinflammatory cytokine release from human cells [245]. It was shown more recently that GBS can use such molecular mimicry to engage a sialic acid–binding surface receptor, Siglec-9, expressed on human neutrophils, leading to negative cell signaling cascades that dampen the oxidative burst and bactericidal activities of phagocytic cell [246].

The properties of group B streptococcal CPS have been studied most thoroughly in serotype III organisms. Sialic acid is a critical element in the epitope of the type III capsule that confers protective immunity. After treatment with sialidase, the altered CPS fails to elicit protective antibodies against group B streptococcal infection. Protective antibodies derived from native type III capsule do not bind to the altered (asialo) capsule backbone structure [247]. Sialidase-treated type III GBS are opsonized more effectively by complement through the alternative pathway and are more readily phagocytosed by human neutrophils in vitro, and sialidase exhibits diminished lethality of the organism in neonatal rats [248,249].

More definitive evidence for the role of type III capsule in virulence is provided by the construction of isogenic capsule-deficient mutants by transposon mutagenesis or targeted allelic replacement [250–252]. Compared with the parent strains, isogenic capsule mutants are susceptible to opsonophagocytosis in the presence of complement and healthy adult neutrophils [253]. Opsonization by complement is a pivotal element in host defense against invasive infections; however, the extent of C3 deposition on GBS by the alternative complement pathway is inversely related to the size and density of their polysaccharide capsule present [253,254]. C3 fragments bound to the acapsular mutant are predominantly in the active form, C3b, whereas the inactive form, C3bi, is predominantly bound to the surface of the parent strain.

The type III group B streptococcal acapsular mutants also are significantly less virulent in animal models of infection. In a model of pneumonia and bacteremia, neonatal rats were inoculated with either the parent strain or an acapsular mutant by intratracheal injection. In animals that received the acapsular mutant, fewer GBS were recovered per gram of lung, more bacteria were associated with resident alveolar macrophages, and the animals became significantly less bacteremic than animals that received the parent strain [255]. Subcutaneous injection of the acapsular mutants in neonatal rats resulted in $LD_{50}$ values that were at least 100-fold greater than the values obtained with the parent strain [251,256]. Mouse passage of various serotypes of GBS was followed by increases in sialylated capsule content that correlated with increased virulence [257]. Taken together, these data provide compelling evidence that the capsule protects the organism from phagocytic clearance during the initial pulmonary phase and the later bacteremic phase of early-onset infection.

## Noncapsular Factors That Interfere with Immune Clearance

The ability of GBS to avoid opsonophagocytosis is enhanced by surface proteins that can act in concert with CPS. Serotype II strains displaying both components of the C protein antigen are more resistant to phagocytic killing than are serotype II strains lacking C protein [258,259]. The b antigen of C protein binds human IgA [260,261], and IgA deposited nonspecifically on the bacterial surface probably inhibits interactions with complement or IgG [262]. A cell surface protease, CspA, targets host fibrinogen, producing adherent fibrin-like cleavage products that coat the bacterial surface and interfere with opsonophagocytic clearance [263]. The group B streptococcal BibA protein binds human C4bp, a component of the classical complement pathway, and increases resistance to phagocytic killing [264]. Finally, certain type Ia group B streptococcal strains can also use the surface anchored b protein to engage Siglec 5 on macrophages and neutrophils and downregulate their innate immune function, a unique example of protein-mediated subversion of a host lectin receptor [265].

After phagocytic uptake of pathogens, neutrophils and macrophages seek to kill the engulfed bacteria by generation of reactive oxygen products and other antimicrobial substances. Streptococci are often thought of as "extracellular pathogens," but these organisms can survive for prolonged periods within the phagolysosome of macrophages [266,267]. Although GBS lack the neutralizing enzyme catalase, they are more than 10 times resistant to killing by hydrogen peroxide than is catalase-positive *S. aureus* [268]. Several mechanisms for enhanced intracellular survival have been identified. The organism possesses an endogenous source of the oxygen metabolite scavenger glutathione [268]. Another defense against oxidative burst killing is the enzyme superoxide dismutase (SodA), as evidenced by the fact that a SodA mutant is highly susceptible to macrophage killing and survives poorly in vivo [269]. Finally, GBS produce an orange carotenoid pigment, a property unique among hemolytic streptococci and genetically linked to the cyl operon encoding β-hemolysin/cytolysin. The free radical scavenging properties of the carotenoid neutralize hydrogen peroxide,

superoxide, hypochlorite, and singlet oxygen, providing a shield against several elements of phagocyte oxidative burst killing [270]. The antioxidant effects of glutathione, SodA, and carotenoid pigment apparently compensate for the lack of catalase and explain the unexpected persistence of GBS within host phagolysosomes.

Cationic antimicrobial peptides, such as defensins and cathelicidins produced by host phagocytes, also are an important component of innate immune defense against invasive bacterial infection [271]. The group B streptococcal *ponA* gene codes for an extracytoplasmic penicillin-binding protein (PBP1a) that promotes resistance to phagocytic killing independent of capsule [272]. Group B streptococcal mutants with deletion of the PBP1a gene are less virulent after lung and systemic challenge, and this is correlated to an increased susceptibility to defensins and cathelicidins [272a]. Another way in which the organism avoids antimicrobial peptide clearance is through the D-alanylation of lipoteichoic acid in the bacterial cell wall; this requires activity of gene products that are encoded by the *dlt* operon. A *dlt*A mutant exhibits decreased negative surface charge that impedes cationic host defense peptides from reaching their cell membrane target of action [273]. Similarly, expression of the pilus backbone protein PilB renders GBS more resistant to killing by cathelicidins and is associated with enhanced phagocyte resistance and systemic virulence [274].

Direct cytotoxicity to host phagocytes represents another important virulence mechanism for immune resistance. The group B streptococcal β-hemolysin/cytolysin toxin produces direct cytolytic injury to macrophages and induces macrophage apoptosis over a longer interval. With highly hemolytic strains or with a large bacterial inoculum, killing of the phagocyte seems to outpace the phagocyte's microbicidal mechanisms, allowing bacterial proliferation in vitro in a murine bacteremia model [270]. Addition of an inhibitor of β-hemolysin/cytolysin blocks cytolysis and reduces apoptosis of macrophages, restoring phagocytic killing [270]. GBS-induced macrophage apoptosis can also occur by a β-hemolysin/cytolysin–independent mechanism regulated, at least in part, by glucose [275]. Signaling pathways involved in GBS-induced programmed cell death of macrophages seem to involve either caspase-3 or calpain activation [276,277].

Deficiencies in the neutrophil response to GBS have been documented in newborn infants. Neutropenia and depletion of the marrow neutrophil storage pool are frequent findings in infants with septicemia [278] and are correlated with poor clinical outcome [212]. Although neutrophilia and an increase in granulocytic stem cells develop in adult rats infected with GBS, severe neutropenia without a change in stem cell counts develops in neonatal rats [279]. Fatal infection in neonatal rats is associated with failure of recovery of depleted myeloid storage pools [280]. The explanation for this finding may be that the proliferative rate of neutrophils in noninfected neonatal animals already is maximal or near-maximal and cannot increase further in response to bacterial challenge [281].

GBS actively contribute to poor mobilization of neutrophils by production of an enzyme that cleaves and inactivates human C5a, a complement component that stimulates neutrophil chemotaxis [82]. Expression of C5a peptidase reduces the acute neutrophil response to sites of infection in C5a knockout mice reconstituted with human C5a [282]. Expression of group B streptococcal C5a peptidase is induced in normal human serum [283]; however, its enzymatic activity is often neutralized, in large part because of naturally occurring IgG antibodies present in many adults [82]. IgG also neutralizes C5a peptidase on the surface of a capsule-deficient group B streptococcal mutant, but fails to neutralize the enzyme on the surface of the intact encapsulated type III parent strain. The capsule serves to protect the cell-associated C5a peptidase from inactivation by naturally occurring antibodies.

## Inflammatory Mediators and Sepsis

When failures in epithelial barrier function and immunologic clearance allow GBS to establish bacteremia in the neonate, sepsis or septic shock develops. Intravenous infusion of GBS in animal models produces similar pathophysiologic changes to human newborn infection, including hypotension, persistent pulmonary hypertension, tissue hypoxemia and acidosis, temperature instability, disseminated intravascular coagulation, neutropenia, and, ultimately, multiple organ system failure. These similarities have allowed in vivo experiments to elucidate the patterns in which the organism activates host inflammatory mediators to induce sepsis and circulatory shock.

Animal models in which GBS are infused intravenously exhibit a biphasic host inflammatory response [284–286]. The acute phase ($\leq$1 hour after infusion) is manifested by increased pulmonary artery pressure and decreased arterial oxygenation and is associated with an increase in serum levels of thromboxanes. Pulmonary hypertension and hypoxemia persist through the late phase (2 to 4 hours), in which a progressive pattern of systemic hypotension, decreased cardiac output, and metabolic acidosis develops together with hematologic abnormalities; organ system dysfunction; and increase in inflammatory markers, such as thromboxanes, tumor necrosis factor (TNF)-α, and prostacyclins. If production of thromboxane and prostacyclin is blocked by inhibition of the cyclooxygenase pathway in rabbits or lambs infused with GBS, decreased myocardial dysfunction and a significant increase in systemic blood pressure are observed [287–289].

Infusion of GBS produces pulmonary hypertension in piglets and isolated piglet lung preparations, suggesting a direct interaction of the organism with target cells in lung microvasculature [290,291]. GBS induce release of vasoactive eicosanoids prostacyclin and prostaglandin $E_2$ from lung microvascular cells [292] and stimulate the host inflammatory mediators leukotriene $D_4$ [293] and thromboxane $A_2$ [294].

The cytokine IL-12 has an important role in the systemic response to group B streptococcal infection. Elevation of IL-12 occurs 12 to 72 hours after challenge in the neonatal rat. Pretreatment with a monoclonal antibody against IL-12 results in greater mortality and intensity of bacteremia, whereas therapeutic administration of IL-12 is associated with a lower mortality rate and bloodstream replication of

the organism [295]. By contrast, IL-1, a known stimulator of cyclooxygenase and lipoxygenase pathways, seems to occupy a proximal position in the deleterious cytokine cascade of septic shock [296]. Treatment with an IL-1 receptor antagonist improves cardiac output and mean arterial pressure, and increases duration of survival in piglets receiving a continuous infusion of GBS [297].

Controversy exists regarding the precise role of TNF-α in neonatal septicemia. TNF-α often is detected in the blood, urine, or cerebrospinal fluid (CSF) of infants with invasive disease [298]. Although infusion of GBS in piglets is associated with TNF-α release during the late phase of hemodynamic response, the TNF-α inhibitor pentoxifylline has only modest effects on pulmonary hypertension, hypoxemia, and systemic hypotension [299]. Marked improvement in these hemodynamic parameters is seen only when pentoxifylline treatment is combined with indomethacin inhibition of thromboxane and prostacyclin synthesis [300]. Serum TNF-α levels in the mouse and rat also increase after challenge; however, administration of polyclonal or monoclonal anti–TNF-α antibody does not affect overall mortality rate in these animal models [300,301].

Studies have sought to establish the components of GBS cell wall that trigger the host cytokine cascade. Host release of IL-l and IL-6 is stimulated by soluble cell wall antigens [302]. Cell wall preparations also cause nuclear factor κB (NF-κB) activation and TNF-α release from human monocytes in a manner requiring CD14 and complement receptor types 3 and 4 [303]. Group B polysaccharide and peptidoglycan are more effective stimulators of TNF-α release from monocytes than lipoteichoic acid or CPS [304]. Knockout mouse studies indicate that cell wall peptidoglycan-induced activation of p38 and NF-κ B depends on the cytoplasmic toll-like receptor (TLR) adapter protein MyD88, but does not require the pattern recognition receptor TLR2 or TLR4 [305]. An additional, undefined secreted factor apparently activates phagocytes through TLR2 and TLR6 [306].

Inhibitor studies have shown that the mitogen-activated protein kinase/JNK signaling pathway is required for the NF-κB–dependent inflammatory response of phagocytes to GBS. Because neither phagocytosis nor oxidative killing of bacteria is affected by JNK inhibition, this pathway may represent a viable therapeutic target for group B streptococcal sepsis [307]. The nitric oxide pathway is implicated in overproduction of proinflammatory cytokines such as IL-6 and initiation of cellular injury during group B streptococcal lung infection [308]. Inducible cyclooxygenase-2 is also stimulated on group B streptococcal infection in human monocytes, likely through the mitogen-activated protein kinase pathway [309]. Infection also stimulates cyclooxygenase-2 and prostaglandin $E_2$ expression in lung tissue in vitro and in vivo. GBS-induced cyclooxygenase-2 and prostaglandin $E_2$ inflammatory response is reduced on treatment with an inducible nitric oxide synthase inhibitor and restored by addition of a nitric oxide donor, showing at least partial regulation by the nitric oxide pathway [310].

Another proinflammatory molecule contributing to the pathogenesis of group B streptococcal septicemia is β-hemolysin/cytolysin. This potent cytoxin acts to stimulate inducible nitric oxide synthase in macrophages, leading to release of nitric oxide [311]. In a mouse model of bacteremia and arthritis, β-hemolysin/cytolysin expression is associated with higher mortality, increased bacterial loads, greater degrees of joint injury, and release of the proinflammatory cytokines IL-6 and IL-1α systemically and intra-articularly [312]. Challenge of rabbits with isogenic group B streptococcal mutants showed that β-hemolysin/cytolysin production was associated with significantly higher degrees of hypotension, increased mortality, and evidence of liver necrosis with hepatocyte apoptosis [313]. Partially purified β-hemolysin/cytolysin preparations produce significant hypotensive actions when infused in rats and rabbits, including death from shock [314]. β-hemolysin/cytolysin also contributes directly to cardiomyocyte dysfunction and apoptosis, which may magnify its role in the pathophysiology of group B streptococcal sepsis [315].

## Blood-Brain Barrier Penetration and Meningitis

The pathophysiology of group B streptococcal meningitis varies according to age at onset. In early-onset disease, autopsy studies show little or no evidence of leptomeningeal inflammation, despite the presence of abundant bacteria, vascular thrombosis, and parenchymal hemorrhage [2,226]. By contrast, infants with late-onset disease usually have diffuse purulent arachnoiditis with prominent involvement of the base of the brain [316]. Similar age-related differences in central nervous system (CNS) pathology are evident in the infant rat model of invasive disease [317]. These histopathologic differences reflect underdevelopment of the host immunologic response in the immediate neonatal period, with a higher proportion of deaths resulting from overwhelming septicemia.

To produce meningitis, GBS must penetrate human brain microvascular endothelial cells, the single-cell layer constituting the blood-brain barrier. Intracellular invasion and transcytosis of human brain microvascular endothelial cell tissue culture monolayers have been shown in vitro [318]. Serotype III strains, which account for most of the isolates causing meningitis, invade more efficiently than strains of other common serotypes. A transposon mutant library of type III GBS was screened in tissue culture assays for alterations in invasiveness. Hypoinvasive mutants were identified with disruptions in *iag*A, sharing homology to genes encoding diglucosyldiacylglycerol synthase. Allelic replacement of *iag*A confirms the in vitro phenotype, and the *iag*A knockout mutant does not produce meningitis in mice [319].

In separate avenues of research, group B streptococcal mutants lacking the fibrinogen receptor FbsA, laminin-binding protein Lmb, or pilus backbone subunit protein PilB also showed reduced adherence or invasion of human brain microvascular endothelial cells in vitro [47,223,320]. More recently, a group B streptococcal mutant lacking the surface-anchored serine-rich repeat motif glycoprotein Srr-1 was attenuated for brain endothelial cell invasion and for production of meningitis in the murine model [321]. At high bacterial densities, invasion by GBS of brain microvascular endothelial cells is

accompanied by evidence of β-hemolysin/cytolysin–induced cellular injury [245]. Correspondingly, β-hemolysin/cytolysin knockout mutants show decreased blood-brain barrier penetration and decreased lethality from meningitis in vivo [245].

The host inflammatory response to GBS contributes significantly to the pathogenesis of meningitis and CNS injury. The initiation of the inflammatory response is triggered through the sentinel function of the blood-brain barrier endothelium, which activates a specific pattern of gene transcription for neutrophil recruitment, including production of chemokines (e.g., IL-8, Groα), endothelial receptors (intercellular adhesion molecule-1), and neutrophil activators (granulocyte-macrophage colony-stimulating factor) [245]. A vascular distribution of cortical lesions in neonatal rats with group B streptococcal meningitis indicates that disturbances of cerebral blood flow contribute to neuronal damage [322]. Inflammation of individual brain vessels can lead to focal lesions, whereas diffuse alterations of cerebral blood flow could cause generalized hypoxic-ischemic injury and cerebral edema [322,323]. Arteriolar dysfunction is associated with the presence of oxygen free radicals thought to be a by-product of the phagocytic killing by infiltrating neutrophils [324]. Group B streptococcal β-hemolysin/cytolysin induces IL-8 and the neutrophil receptor intercellular adhesion molecule-1, promoting neutrophil migration across polar brain microvascular endothelial cells (BMEC) monolayers, suggesting that the toxin is crucial to this particular manifestation of CNS disease [245].

TNF-α production by astrocytes, microglial cells, and infiltrating leukocytes seems to contribute to apoptosis of hippocampal neurons [325], further increasing blood-brain barrier permeability during group B streptococcal meningitis [326]. Intraventricular inoculation of newborn piglets with GBS results in an early sharp increase in CSF TNF-α levels, followed shortly by prostaglandin release and neutrophil influx [327]. The magnitude of the observed TNF-α response and inflammatory cascade is markedly increased when an isogenic nonencapsulated mutant is tested in place of the type III parent strain [327], suggesting that a component of the underlying cell wall and not capsule is responsible for inducing the CNS inflammatory response. GBS signal through TLR2 to activate and stimulate nitric oxide production by microglia cells, resulting in neuronal destruction [328]. Simultaneous intracisternal administration of dexamethasone with GBS in the rat model leads to a marked reduction in subarachnoid inflammation, vasculopathy, and neuronal injury [322]. In the course of experimental group B streptococcal meningitis, microglial apoptosis is triggered via the cysteine protease caspase-8 and is hypothesized to represent a self-dampening mechanism that prevents overstimulation of brain inflammation [329].

## HOST FACTORS RELATED TO PATHOGENESIS

### Risk Factors for Early-Onset Infection

Infant and maternal factors that increase risk for early-onset group B streptococcal infection are listed in Table 12–2. The most obvious risk determinant is exposure through maternal colonization at delivery. Maternal race or ethnicity is correlated significantly with early-onset group B streptococcal disease, with enhanced risk for infants born to African American and Hispanic mothers compared with infants born to white mothers [117,143,330]. Risk correlates directly with density of maternal genital inoculum [132]. Symptomatic early-onset disease develops in 1% to 2% of infants born to colonized women who do not receive IAP, but this rate is considerably increased if there is premature onset of labor (before 37 weeks of gestation) (15%) [331], chorioamnionitis or interval between rupture of membranes and delivery longer than 18 hours (11%) [176,331], twin pregnancy (35%) [332,333], or maternal postpartum bacteremia (10%) [334].

**TABLE 12–2** Risk Factors for Early-Onset Group B Streptococcal Disease

| Risk Factor | Representative Reference Nos. |
|---|---|
| Maternal colonization at delivery | 3,109,331 |
| High-density maternal colonization | 114,132,176 |
| Rupture of membranes before onset of labor | 176,330 |
| Preterm delivery <37 wk gestation | 330 |
| Prolonged rupture of membranes ≥18 hr | 330,706 |
| Chorioamnionitis | 679 |
| Intrapartum fever ≥38° C (≥100.4° F) | 330 |
| Intrauterine monitoring | 330,706 |
| Maternal postpartum bacteremia | 334 |
| Multiple pregnancy | 332,333 |
| Group B streptococcal bacteriuria or urinary tract infection | 330 |
| Cesarean section | 3,176 |
| Low level of antibody to infecting CPS type | 340 |
| Young maternal age (<20 yr) | 330,706 |
| Previous infant with invasive group B streptococcal infection | 707 |
| Maternal race/ethnicity | 110,170,143 |

*CPS, capsular polysaccharide.*

Maternal group B streptococcal bacteriuria and urinary tract infection are predictive of high-inoculum colonization, which enhances infant risk for invasive infection [335]. Heavy group B streptococcal colonization in the second trimester of pregnancy also is associated with increased risk of delivering a preterm infant with low birth weight [336]. Among infants born to mothers with premature rupture of membranes at term gestation, maternal chorioamnionitis and colonization with GBS are strong predictors of neonatal infection [337]. Vaginal colonization with GBS is an independent risk factor for the development of chorioamnionitis [338].

Prolonged interval after rupture of membranes (>18 hours) before delivery and preterm delivery (<37 weeks' gestation) often are concomitant risk factors in neonates with early-onset group B streptococcal infection. The estimated incidence of early-onset group B streptococcal infection is 10 times higher in preterm than in term neonates [176,193]. Even with correction for preterm delivery, twin pregnancy is an independent risk factor for

invasive early-onset group B streptococcal septicemia [332]. The explanation for the increased risk in twins likely relates to genetic factors regulating host susceptibility, lack of specific antibody to the infecting strain in the mother, similar density of maternal colonization, and virulence of disease-producing strains [332,333].

## Antibody to Capsular Polysaccharide

Lancefield showed that antibodies directed against capsular type-specific surface antigens of GBS protected mice from lethal challenge [339]. Baker and Kasper [340] showed in 1976 that neonatal risk for type III group B streptococcal disease correlated with a deficiency of antibody to type III CPS in maternal sera. A low concentration of type III CPS-specific antibodies was shown in sera from 32 infants with invasive disease [341]. Women with type III group B streptococcal genital colonization at delivery whose infants remained well more often had antibody concentrations exceeding 2 μg/mL of type III–specific antibodies in their sera than women whose infants developed type III early-onset disease. Quantitative determination of antibodies to type III group B streptococcal polysaccharide by enzyme-linked immunosorbent assay (ELISA) indicated that these antibodies were predominantly IgG [342,343]. Gray and coworkers [344] noted a similar correlation between low concentrations of type II–specific antibodies in maternal delivery sera and susceptibility of infants to invasive infection. Approximately 15% to 20% of pregnant women have a concentration of IgG to CPS in their delivery serum presumed to protect against invasive disease. These higher concentrations are present significantly more often in sera of women colonized with the homologous group B streptococcal type than in noncolonized women [117,120,345].

Attempts have been made to quantify the concentration of antibody to group B streptococcal CPS in maternal serum conferring protection against invasive disease in infants. Using ELISA standardized by quantitative precipitation [346], 1 μg/mL, 0.2 μg/mL, and 1.3 μg/mL of IgG to serotypes Ia, Ib, and III were protective in experimental models of infection [347–350]. A prospective, multicenter, hospital-based, case-control study of mothers delivering infants with type Ia, III, or V early-onset sepsis and matched colonized control mothers delivering healthy infants quantified the maternal serum concentrations of type Ia, III, and V CPS-specific IgG at delivery that protected neonates from early-onset disease. For types Ia and III, maternal IgG concentrations of 0.5 μg/mL or greater corresponded to a 90% risk reduction. For type V, the same antibody concentration corresponded to 70% risk reduction [351]. The findings of Lin and colleagues [352,353] agreed in principle, but described a higher concentration of CPS-specific IgG as the correlate for protection against type Ia or III group B *Streptococcus*. Neonates whose mothers had at least a 5 μg/mL concentration of IgG to type Ia CPS in their sera had an 88% lower risk of developing early-onset disease compared with neonates whose mothers had concentrations less than 0.5 μg/mL. Neonates whose mothers had at least a 10 μg/mL concentration of IgG to type III CPS in their sera by ELISA had a 91% lower risk for early-onset disease compared with neonates whose mothers had concentrations less than 2 μg/mL. In contrast, antibody to the group B polysaccharide does not confer protection against invasive infant disease [354].

Low concentrations of IgG to type III CPS are uniformly found in acute sera of infants with late-onset type III infection [340,355–357]. In a study of 28 infants with late-onset bacteremia and 51 with meningitis, Baker and coworkers [341] detected low levels of antibodies to type III CPS in acute sera from all infants. These low levels in term infants with late-onset type III group B streptococcal infection correlated with maternal levels at delivery [341,356].

It is important to employ antigens with "native" or intact type III polysaccharide specificity in evaluating human immunity to type III GBS [358,359]. Kasper and colleagues [247] used gently extracted (native) and hydrogen chloride–treated (core) type III group B streptococcal and pneumococcal type 14 antigens to study sera from infants with invasive type III infection and their mothers. Concentrations of type III–specific antibodies in sera of sick infants and their mothers had uniformly low binding to fully sialylated, type III polysaccharide. Opsonic immunity correlated with antibodies to fully sialylated, but not to desialylated type III polysaccharide or to type 14 pneumococcal antigen. Among infants recovering from type III disease in whom a significant increase in antibodies to the fully sialylated polysaccharide developed, no detectable increase in the acid-degraded or core antigen was seen. Human immunity to type III GBS relates to antibodies to capsular type III polysaccharide with an intact protective epitope.

An extension of this concept comes from studies in which adults have been immunized with either type III polysaccharide or pneumococcal polysaccharide vaccine [358]. Adults with low concentrations of type III antibodies in their sera before immunization responded to type III polysaccharide vaccine with a significant increase in type III–specific antibodies. This response was not observed when the structurally related type 14 pneumococcal polysaccharide was used as an immunizing agent. Among adults with moderate to high levels of antibodies to type III polysaccharide, however, significant increases in this antibody developed after pneumococcal polysaccharide vaccine. This finding suggests that the structurally similar antigen could elicit secondary B-cell proliferation in previously primed adults.

## Mucosal Immune Response

Genital colonization with GBS may elicit specific antibody responses in cervical secretions. Women with group B streptococcal type Ia, II, or III rectal or cervical colonization have markedly elevated levels of IgA and IgG to the colonizing serotype in their cervical secretions compared with cervical secretions from noncolonized women. Elevated amounts of IgA and IgG to the protein antigen R4 also have been found in women colonized with type III strains (most type III strains contain R4 antigen) compared with noncolonized women [360,361]. These findings suggest that a mucosal immune response occurs in response to colonization with GBS. Induction of mucosal antibodies to surface group B streptococcal polysaccharide or protein antigens may prevent genital colonization, diminishing vertical transmission of infection from mothers to infants.

## Complement and Antibody Interactions

Shigeoka and colleagues [240] showed that specific antibody was required and that the classical complement pathway maximized opsonization of types I, II, and III GBS [362]. Capsule-specific antibodies also facilitated alternative complement pathway–mediated opsonization and phagocytosis of type III GBS [248]. The relationship between antibody concentration and the rate constant of killing of type III strains was found to be linear and determined, at least in part, by the number of antibody molecules bound per organism [363,364]. IgG subclasses 1, 2, and 3 and IgM were shown to support opsonic activity in vitro [365–368], and an IgA monoclonal antibody activated C3 and conferred protection against lethal infection [369]. Encapsulated and genetically derived acapsular mutants of type III GBS deposit C3 and support its degradation, but an inverse correlation exists between extent of encapsulation and C3 deposition by the alternative pathway [253,370]. Among infants surviving type III group B streptococcal meningitis, transient development of type-specific antibodies, predominantly IgM, supported opsonophagocytosis during convalescence [371]. When specific IgM concentrations declined, and despite maturation of complement synthesis, opsonophagocytosis of type III organisms by these infant sera remained poor.

In contrast with these findings for type III strains, clinical isolates of type Ia GBS can be efficiently opsonized, phagocytosed, and killed by neutrophils from healthy adults by the classical complement pathway in the absence of antibodies [372]. Surface-bound CPS of type Ia strains mediates C1 binding and activation [373,374]. For type Ib GBS, a role for capsule size and density in modulating C3 deposition has been reported [254]. Variability among these strains in their capacity for C3 deposition by the alternative pathway also has been shown [375].

Type II strains possessing α C and β C proteins are more resistant to opsonization than strains lacking both proteins [258]. Strains lacking type II polysaccharide but having both C proteins are readily opsonized. R protein or an IgA-mediated blocking effect may modulate phagocytosis of some type II strains. Despite the complexity of type II opsonins, it is clear that complement is essential and that integrity of the classical complement pathway is critical. Evaluation of neutrophil-mediated killing of types IV and V GBS also reveals the importance of complement and CPS-specific antibodies [376,377]. When complement is limited, type-specific antibodies facilitate killing. In sufficient concentration, agammaglobulinemic serum promotes opsonization, phagocytosis, and killing of types IV and V GBS.

During the course of septic shock caused by GBS, complement components are consumed. Cairo and associates [378] found a significant association between low levels of total hemolytic complement and fatal outcome from neonatal bacterial sepsis, including GBS. A critical role for C3 activation through the alternative pathway has been shown for potent GBS-induced TNF-α release [379]. This finding and the observation that complement-dependent uptake of CPS by marginal zone B cells seems necessary for an effective immune response to CPS [380] may partially explain this finding. The β component of C protein also can bind human factor F, a negative regulator of complement activation, evading complement attack [381].

## Phagocyte Function

Smith and associates [382] examined the role of complement receptors CR1 and CR3 in the opsonic recognition of types Ia and III GBS by neutrophils from healthy neonates and adults. Selective blockade of CR3 or of CR1 and CR3 inhibited killing for each serotype by neutrophils from neonates. These experiments indicated the importance of complement receptor function to opsonization, phagocytosis, and killing of GBS by neutrophils. Whether deficient complement receptor function contributes to susceptibility of neonates to invasive infection is unknown. A role for CR3 also has been shown in nonopsonic recognition of GBS by macrophages [383].

Yang and coworkers [384] performed selective blockade of neutrophil receptors in experiments with type III GBS opsonized with immunoglobulin. Antibodies to neutrophil Fc receptor III (FcR III) inhibited phagocytosis of opsonized bacteria to an extent exceeding that of CR3. Noya and colleagues [385] showed a substantial role for neutrophil FcR II in mediating ingestion of type III GBS opsonized in complement-inactivated serum. When complement receptor function was allowed, FcR II participation no longer was requisite for occurrence of phagocytosis. Participation by FcR and complement receptor in phagocytosis of GBS by peritoneal macrophages also has been reported [386].

Christensen and coworkers [279,281] and others [278] have addressed the explanations for the profound neutropenia often observed in fulminant group B streptococcal infection in neonates. The nearly maximal proliferative rate of granulocytic stem cells in noninfected neonatal animals led to the suggestion that neutrophil transfusion might improve the survival of human neonates with group B streptococcal infection in whom neutrophil storage pool depletion was documented [278,378]. In experimental infection with type III GBS, monoclonal IgM antibody to type III polysaccharide stimulated the release of neutrophils from storage pools into the bloodstream and improved neutrophil migration to the site of infection [387]. This facilitation of neutrophil function by type III–specific antibody improved survival in animals only if the antibody was administered when neutrophil reserves were intact (very early in infection) [388]. Antibody recipients did not become neutropenic and did not experience depletion of their neutrophil reserves. These and similar in vitro and in vivo studies using commercial preparations of immunoglobulin for intravenous administration [389–391] emphasize the importance of IgG in facilitating the neutrophil inflammatory response.

Reticuloendothelial clearance of opsonized GBS also is less efficient in experimental infection of young animals [392,393], as are lung macrophage postphagocytic oxidative metabolic responses [394]. An age-related impairment in clearance of GBS from the lungs has been reported for infant compared with adult rats and for preterm compared with term animals [395,396]. Animal age is a more important determinant of bacterial elimination from the

lung than amount of polysaccharide capsule, although encapsulated strains are ingested less efficiently and in fewer numbers in infant rats than in adult rats [255].

## Other Factors Related to Pathogenesis

Fibronectin is a high-molecular-weight glycoprotein that participates in adherence and functions as a nonspecific opsonin. The observation that septic neonates have significantly lower fibronectin levels than healthy age-matched controls stimulated evaluation of the possible role of fibronectin in the pathogenesis of group B streptococcal infection [397]. Soluble fibronectin binds poorly to GBS in the absence of other opsonins [398]. GBS do adhere to immobilized fibronectin, however. Fibronectin also enhances ingestion by neutrophils, monocytes, or macrophages of GBS opsonized with type-specific antibody [399–401] and may promote TNF-α production by macrophages [402]. It also has been shown that interaction of type III CPS with the lectin site of CR3 effectively triggers phagocytosis of type III organisms by nonimmune serum. Use of this mechanism provides a potential explanation for the infrequency with which invasive infection develops in susceptible individuals exposed to GBS [403].

It has been hypothesized that some individuals may have a genetically based predisposition to infection with GBS. Among 34 Swedish mothers of infants with group B streptococcal disease, Grubb and coworkers [404] identified a surplus of individuals possessing G3m(5) and a deficit of individuals with G1m(1). Thom and colleagues [405] found deficits of G1m(1) and Km(1) and an increased incidence of G2m(23) among mothers of infected infants. The distribution of allotypic markers may influence responses to protein and polysaccharide antigens. G2m(23) is a marker of $IgG_2$, the subclass most often associated with brisk immune responses to polysaccharide antigens. There could be genetically determined explanations for the deficiency of IgG subclasses [406], high IgM concentration with divergent ratio of IgG to IgM [407,408], and chronic colonization state without immunologic response [409] described in Swedish mothers of infants with group B streptococcal disease. In a study of women in the United States who delivered infants with invasive type III group B streptococcal disease, postpartum immunization with type III group B streptococcal polysaccharide elicited immune responses similar to those in control women [410].

# PATHOLOGY

Pathologic findings in early-onset infection depend on the duration of exposure to GBS before or during birth. Intrauterine death has been attributed to group B streptococcal infection [209,409,411] and is considered to be a common cause of mid-gestational fetal loss in women who have experienced either vaginal hemorrhage or septic abortion [411,412]. Fetal membrane infection with GBS can result in spontaneous abortion or premature rupture of membranes or both, as suggested by Hood and associates in 1961 and others [413–415].

Becroft and colleagues [416] noted histologic changes consistent with congenital pneumonia in live-born neonates whose autopsy lung cultures yielded GBS. Numerous placentas showed amnionitis in mothers whose infants had fulminant pneumonia and died within 36 hours after birth. Findings were sufficient in stillborn infants to indicate that death occurred as a direct consequence of group B streptococcal intra-amnionitis infection and intrauterine pneumonia. deSa and Trevenen [412] described pneumonitis with pulmonary interstitial and intra-alveolar inflammatory exudates in 15 infants weighing less than 1000 g who had intra-amniotic infection; 6 infants were stillborn, and 9 died within hours of birth. Placental examination revealed chorioamnionitis. In a primate model of infection, intra-amniotic inoculation of GBS elicited fulminant early-onset neonatal infection [215]. Microscopy of lung tissue revealed organisms within membrane-bound vacuoles of alveolar epithelial cells; interstitial fibroblasts; and organisms present within tissue macrophages of the liver, spleen, and brain, documenting their rapid dissemination.

Amnionitis in association with early-onset group B streptococcal sepsis (1) is more frequently detected when death occurs shortly after birth, (2) is a common finding when membranes have been ruptured 24 hours or longer before delivery [211,412,413], and (3) can be clinically silent in some women. GBS can enter the amniotic fluid cavity through ruptured or intact membranes [417], allowing fetal aspiration of infected fluid and subsequent pulmonary lesions or bacteremia, without eliciting a local inflammatory response or maternal signs of intra-amniotic infection.

Among neonates with fatal early-onset group B streptococcal disease, pulmonary lesions are the predominant pathologic feature. The association between pulmonary inflammation and formation of hyaline membranes was first noted by Franciosi and coworkers [2]. Subsequently, autopsy findings in early-onset disease cases revealed "atypical" pulmonary hyaline membranes in most [2,210,211], and these corresponded with radiographic features consistent with respiratory distress syndrome in some neonates [133]. GBS were frequently present within these membranes, and in some infants these were composed almost entirely of streptococci, rendering them basophilic in hematoxylin and eosin preparations [214]. Katzenstein and colleagues [214] postulated that invasion of alveolar cells and capillary endothelial cells by GBS resulted in exudation of plasma proteins into the alveoli, deposition of fibrin, and hyaline membrane formation. Immune complex–mediated injury to the lung was proposed by Pinnas and associates [418] as a mechanism for this hyaline membrane formation.

Histologic evidence for pneumonia was found historically in approximately 80% of patients with fatal early-onset group B streptococcal pneumonia [210,418,419]. The associated radiographic pattern could be focal, extensive, lobular, or bronchial, involving one or more lobes. The typical histologic features of congenital pneumonia (i.e., alveolar exudates composed of neutrophils, erythrocytes, and aspirated squamous cells, with edema and congestion) were observed either independently or in association with hyaline membrane formation. In neonates with fulminant, rapidly fatal group B streptococcal infection, the cellular inflammatory response was less pronounced. An

interstitial inflammatory exudate is a consistent feature of fatal infection, as is pulmonary hemorrhage, which can range from focal interstitial to extensive intra-alveolar bleeding.

In CNS infection, age at onset predicts distinctive morphologic findings in the brain and meninges. In early-onset meningitis, little or no evidence of leptomeningeal inflammation is seen in three quarters of infants [2,176,226], although purulent meningitis can be observed occasionally. This lack of inflammatory response can be the result of rapidly progressive infection, with an interval of only a few hours from onset of clinical illness until death, or can reflect inadequate host response to infection, or both. Bacteria generally are found in large numbers, and perivascular inflammation, thrombosis of small vessels, and parenchymal hemorrhage frequently are noted [226]. In some preterm infants surviving septic shock caused by early-onset group B streptococcal infection, periventricular leukomalacia, a condition characterized by infarction of the white matter surrounding the lateral ventricles, develops [420]. Infants with fatal late-onset meningitis almost always have a diffuse purulent leptomeningitis, especially prominent at the base of the brain, with or without perivascular inflammation and hemorrhage [2,421]. Infants surviving severe meningitis have multiple areas of necrosis, and abscess formation can be found throughout the brain by neuroimaging or later at autopsy.

This age-related inflammatory response in infants with group B streptococcal infection has a parallel in the infant rat model of meningitis [317]. Young infant rats 5 to 10 days of age have numerous bacteria distributed in a perivascular pattern, and organisms can extend transmurally into vessel lumina. These animals generally have no evidence of acute leptomeningeal inflammation or edema. By contrast, 11- to 15-day-old animals have leptomeningitis and cerebritis with a pronounced infiltration of neutrophils and macrophages around meningeal vessels and in perivascular spaces within the cerebral cortex. Because response to infection becomes more efficient within a few weeks after birth, the absence of inflammation in the brain and meninges of infant rats and of human neonates with early-onset group B streptococcal infection may relate to chemotactic defects [241], exhaustion of neutrophil stores [280,281], reticuloendothelial system immaturity [392], or to other deficits in the host response to infection.

# CLINICAL MANIFESTATIONS AND OUTCOME

## EARLY-ONSET INFECTION

When the incidence of neonatal infection caused by GBS increased dramatically in the 1970s [422], a bimodal distribution of cases according to age at onset of signs became apparent. Two syndromes related to age were described in 1973 by Franciosi and associates [2] (acute and delayed) and by Baker and colleagues [3] (early and late). Early-onset infection typically manifests within 24 hours of birth (an estimated 85% of cases; median age 12 hours), but it can become evident during the second 24 hours of life (an estimated 10% of cases) or at any time during the subsequent 5 days. Premature infants often experience onset at or within 6 hours of birth; infants with onset after the first 24 hours of life usually are of term gestation [208]. Late-onset infections occur at 7 to 89 days of age (median age 37 days). Classification of syndromes by age at onset is useful, but there also is a continuum in age at onset. A few patients with early-onset disease can present at 5 or 6 days of age, and late late-onset infection can affect 3- to 6-month-old infants, especially infants with gestational age of less than 28 weeks [150]. Onset beyond 6 months of age can herald the presentation of human immunodeficiency virus (HIV) infection or other immune system abnormalities [423].

Early-onset group B streptococcal infection often affects neonates whose mothers have obstetric complications associated with risk for neonatal sepsis (onset of labor before 37 weeks of gestation, prolonged interval at any gestation between rupture of membranes and delivery, rupture of membranes ≥18 hours before delivery, intrapartum fever >38° C [>100.4° F], intra-amniotic infection, early postpartum febrile morbidity, and twin births) (Table 12–3). A nearly threefold risk of early-onset

**TABLE 12–3** Features of Group B Streptococcal Disease in Neonates and Infants

| Feature | Early-Onset (<7 Days) | Late-Onset (7-89 Days) | Late Late-Onset (>89 Days) |
|---|---|---|---|
| Median age at onset | 1 day | 37 days | >3 mo |
| Incidence of prematurity | Increased | Increased | Common |
| Maternal obstetric complications | Frequent (70%) | Preterm delivery | Varies |
| Common manifestations | Septicemia (80%-85%) | Meningitis (25%-30%) | Bacteremia without a focus (common) |
| | Meningitis (5%-10%) | Bacteremia without focus (65%) | Bacteremia with a focus (uncommon) |
| | Pneumonia (10%-15%) | Soft tissue, bone, or joint pneumonia (5%-10%) | |
| CPS types isolated | Ia (~30%) | III (~60%) | Several |
| | II (~15%) | Ia (~25%) | |
| | III (30%) | V (~15%) | |
| | V (20%) | | |
| Case-fatality rate | 3%-10% | 1%-6% | Low |

*CPS, capsular polysaccharide.*

group B streptococcal disease has been observed when six or more vaginal examinations are performed before delivery [424]. The incidence of infection correlates inversely with the degree of preterm birth, and group B *Streptococcus* is the most frequent pathogen associated with early-onset sepsis in neonates with very low birth weight (<1500 g) [425]. One fourth of infants with early-onset disease historically were born before 37 weeks' gestation, but this number has increased since the introduction of routine prenatal culture screening and IAP for women colonized with GBS [150].

Early-onset group B streptococcal infection can occur in term neonates with no defined maternal risk factors other than colonization. In such cases, recognition is often delayed until the appearance of definite signs of sepsis (e.g., tachypnea, apnea, hypotension), but more subtle signs usually precede these overt manifestations. One report found that one third of healthy term neonates with early-onset group B streptococcal infection were identified solely on the basis of evaluation for maternal intrapartum temperature exceeding 38° C (100.4° F) [426].

The three most common expressions of early-onset infection are bacteremia without a defined focus of infection, pneumonia, and meningitis. In the 21st century, bacteremia without a focus occurs in 80% to 85%, pneumonia occurs in 10% to 15%, and meningitis occurs in 5% to 10% of infants [150]. Bacteremia is often detected in neonates with the latter two presentations, but not always. Regardless of site of involvement, respiratory signs (apnea, grunting respirations, tachypnea, or cyanosis) are the initial clinical findings in more than 80% of neonates. Hypotension is an initial finding in approximately 25%. Infants with fetal asphyxia related to group B streptococcal infection in utero can have shock and respiratory failure at delivery [427]. Additional signs include lethargy, poor feeding, hypothermia or fever, abdominal distention, pallor, tachycardia, and jaundice.

Pneumonia occurs in 10% to 15% of infants with early-onset infection, and virtually all of these infants have acute respiratory signs. Most have these respiratory findings in the first few hours of life (many at birth) or within the first 24 hours of life [210]. Among 19 infants with group B streptococcal congenital pneumonia at autopsy, 89% had 1-minute Apgar scores of 4 or less, indicating in utero onset of infection [208]. Radiographic features consistent with and indistinguishable from those of surfactant deficiency are present in more than half of these neonates (Fig. 12–6). Treatment with surfactant improves gas exchange in most, although the response is slower than in noninfected infants, and repeated surfactant doses often are needed [239]. Infiltrates suggesting congenital pneumonia (Fig. 12–7) are present in one third of infants. Increased vascular markings suggesting the diagnosis of transient tachypnea of the newborn or pulmonary edema can occur. Occasionally, respiratory distress is present in the absence of radiographic abnormalities, appearing as persistent fetal circulation and pulmonary hypertension [419,428]. Small pleural effusions and cardiomegaly can occur.

Meningitis occurs in 5% to 10% of neonates with early-onset infection. Neonates with meningitis often have a clinical presentation early in the course that is identical to presentation of neonates without meningeal involvement. Respiratory distress can be the most common initial sign, and in 27 infants with early-onset meningitis, seizures were never a presenting feature [429]. Examination of CSF is the only means to exclude meningitis, a finding that requires modification of supportive and specific chemotherapy (see “Treatment” later on). Seizures occur during the first 24 hours of therapy in nearly 50% of infants with meningitis. Persistent seizures, semicoma or coma, and a CSF protein concentration greater than 300 mg/dL are associated with a poor prognosis [430–432].

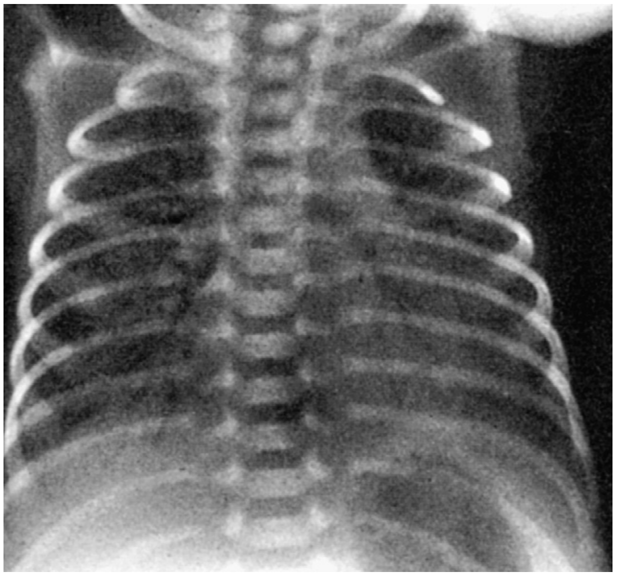

**FIGURE 12–6** Chest radiograph from an infant with early-onset group B streptococcal septicemia shows features consistent with respiratory distress syndrome of the newborn.

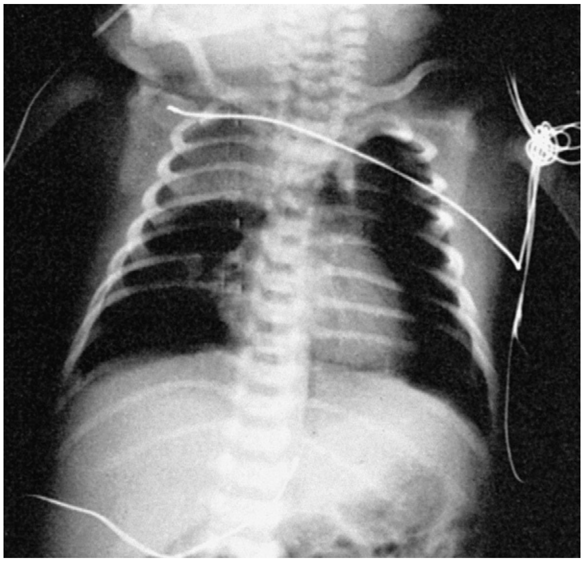

**FIGURE 12–7** Chest radiograph shows right upper and lower lobe infiltrates as manifestations of early-onset group B streptococcal pneumonia in an infant.

**TABLE 12–4** Fatality Rates in Early-Onset Group B Streptococcal Infection

| | Case-Fatality Rate (%) by Birth Weight (g) or Gestational Age (wk) | | | | |
|---|---|---|---|---|---|

| Schrag et al [12] (1993-1998) | | 30 (≤33 wk) | | 10 (34-36 wk) | 2 (≥37 wk) |
| Phares et al [150] (1999-2005) | | 20 (<37wk) | | | 3 (≥37 wk) |

The case-fatality rate for the nearly 300 neonates with early-onset infection summarized by Anthony and Okada [422] in 1977 was 55%. Current data indicate much lower rates of 2% to 10%. Features associated with fatal outcome include a low 5-minute Apgar score, shock, neutropenia, pleural effusion, apnea, and delay in treatment after onset of symptoms [170,212,427]. Fatal infection also occurs significantly more often among premature than among term neonates (Table 12–4). In 1981, Pyati and colleagues [433] reported a case-fatality rate of 61% among 101 preterm neonates who had early-onset group B streptococcal infection. Infants with a birth weight greater than 1500 g had a fatality rate of 14%, however. Contemporary data document that the risk of death among preterm cases is 20%—nearly 8-fold that of term infants for whom infection was fatal in 3% of cases [150].

## LATE-ONSET INFECTION

Late-onset group B streptococcal infection historically affected term infants 7 to 89 days of age who had had an unremarkable maternal obstetric and early neonatal history. Contemporary data indicate that at least half of infants with late-onset disease now are born before 37 weeks of gestation [150]. Late-onset disease has a lower fatality rate (1% to 6%) than early-onset disease. Clinical expressions of late-onset disease include bacteremia without a focus of infection (65% of infants), meningitis (25%), bacteremic cellulitis or osteoarthritis (2% to 3% each), and pneumonia (3%) (see Table 12–3) [150].

Bacteremia without a detectable focus of infection is the most common clinical expression of late-onset group B streptococcal disease [434]. Bacteremia without a focus typically manifests with nonspecific signs (i.e., fever, poor feeding, irritability). Diagnosis results from the practice of obtaining routine blood cultures in febrile infants during the first few weeks of life to exclude serious bacterial infection as an underlying cause. These infants often are mildly ill, but failure to initiate antimicrobial therapy in a timely manner can result in progression to shock, especially in preterm infants, or extension of infection to distant sites such as the CNS. Either transient or persistent bacteremia can occur. Approximately 3% of infants with late-onset bacteremia without a focus die; survivors typically recover without sequelae after treatment.

The presenting signs in infants with late-onset meningitis almost always include fever, irritability or lethargy or both, poor feeding, and tachypnea. Upper respiratory tract infection precedes late-onset meningitis in 20% to 30% of infants, suggesting that alteration of mucosal barrier by respiratory viral illness might facilitate entry of GBS into the bloodstream [2,3,430]. In contrast to early-onset infection, grunting respirations and apnea are less frequent initial findings, and their presence suggests rapidly progressive, fulminant infection. Apnea or hypotension is observed in less than 15% of patients, but there is a spectrum in clinical severity of illness at presentation. Some infants appear clinically well a few hours before initial evaluation and present with seizures, poor perfusion, neutropenia, and large numbers of gram-positive cocci in the CSF. These patients often have a rapidly fatal course, or if they survive, they are left with devastating neurologic sequelae. Leukopenia or neutropenia at the time of diagnosis has been correlated with fatal outcome in these infants [212].

Other initial findings associated with increased risk for fatal outcome or permanent neurologic sequelae include hypotension, coma or semicoma, status epilepticus, absolute neutrophil count less than 1000/mm$^3$, and CSF protein level greater than 300 mg/dL [212,422,430,432]. These findings most likely reflect a high bacterial inoculum in the CSF and cerebritis. Subdural effusions, which usually are small, unilateral, and asymptomatic, are found in 20% of patients with late-onset meningitis. These are not associated with any permanent sequelae. Subdural empyema, obstructive ventriculitis, large infarctions, and encephalomalacia are uncommon complications.

## LATE LATE-ONSET INFECTION

Infections in infants older than 89 days of age can account for 20% of cases of late-onset disease [435]. The terms *very late onset*, *late late-onset*, and *beyond early infancy* have been applied to disease in these infants. Most of these infants have a gestational age of less than 35 weeks. The need for prolonged hospitalization and the immature host status in these infants probably contributes to infection beyond the interval for term neonates. Bacteremia without a focus is a common presentation. Occasionally, a focus for infection, such as the CNS, intravascular catheter, or soft tissues, is identified (see Table 12–3). In the outpatient setting, infants older than 89 days of age are likely to have a temperature greater than 39° C (>102.2° F) and a white blood cell count exceeding 15,000/mm$^3$ [434]. A viral infection can precede the onset of bacteremia [436]. When there are no other apparent risk factors for late late-onset infection in a term infant, immunodeficiency including HIV infection should be considered [437,438].

## SEPTIC ARTHRITIS AND OSTEOMYELITIS

The clinical features of 20 infants with group B streptococcal septic arthritis alone and 45 infants with osteomyelitis (with or without concomitant septic arthritis) are shown in Table 12–5. The mean age at diagnosis of osteomyelitis (31 days) is greater than that for septic arthritis (20 days). The mean duration of symptoms is shorter for septic arthritis than for osteomyelitis (1.5 days versus 9 days). In some infants with osteomyelitis, failure to move the involved extremity since hospital discharge after birth, or shortly thereafter, may be noted; this lack of movement can persist for 4 weeks before the diagnosis is made [439].

Decreased motion of the involved extremity and evidence of pain with manipulation, such as lifting or diaper changing, are common signs of bone infection. Warmth or erythema can occur occasionally [440,441]; a history of fever is reported in only 20% of infants. The paucity of signs suggesting infection and the finding of pseudoparalysis have led to an initial diagnosis of Erb palsy and to assessment for possible child abuse [439,442,443]. In several infants, osteomyelitis of the proximal humerus has been associated with findings on nerve conduction studies consistent with brachial plexus neuropathy [444,445], and in one infant, sciatic nerve injury at the level of the pelvis caused footdrop in association with iliac osteomyelitis [446].

Physical findings include fixed flexion of the involved extremity, mild swelling, evidence of pain with passive motion, decreased spontaneous movement, and, in a few infants, erythema and warmth. Lack of associated systemic involvement is the rule, although osteomyelitis in association with meningitis, peritonitis, and overwhelming sepsis with congestive heart failure has been reported [441,442,447–449].

When infants with septic arthritis alone are compared with infants with osteomyelitis, infants with septic arthritis more often have lower extremity involvement, with the hip joint predominating [447,450]. By contrast, more than half of the reported infants with osteomyelitis have had involvement of the humerus, and in infants for whom the location was specified, the proximal humerus predominated [439,442,447,451]. Osteomyelitis involving both proximal humeri has been described [448]. Involvement of the femur, vertebrae, or small bones occurs occasionally [452,453]. Usually, only one bone is affected, although infection involving two adjacent bones or multiple nonadjacent bones can occur rarely [448,454,455]. Although most infants with humeral osteomyelitis have had concomitant infection in the shoulder joint, isolated septic arthritis of the shoulder joint has not been reported.

Group B streptococcal bone and joint infections have a good prognosis. At evaluation 6 months to 4 years after diagnosis, 17 (90%) of 19 infants with osteomyelitis had normal function in the affected extremity.* Residual shortening and limitation of motion of the humerus were noted in a patient who had overwhelming sepsis of acute onset, with congestive heart failure and osteomyelitis involving noncontiguous sites [447]. Growth disturbance can result as a consequence of subluxation of the hip joint after septic arthritis.

Although septic arthritis and osteomyelitis are considered manifestations of late-onset disease, osteomyelitis seems to represent a clinically silent early-onset bacteremia with seeding of a bone and then later onset of clinical expression of infection. An episode of asymptomatic bacteremia with a birth trauma–induced nidus in the proximal humerus could allow localization of bacteria to the bone. Because lytic lesions take more than 10 to 14 days to become radiographically visible, the presence of such lesions on radiographs obtained at hospital admission suggests long-standing infection (Fig. 12–8). Non–type III strains are overrepresented among infants with osteomyelitis, which is consistent with the hypothesis that, in at least some patients, early-onset bacteremia with bony localization of infection may have occurred.

**TABLE 12–5** Clinical Features of Group B Streptococcal Bone and Joint Infections*

| Feature | Septic Arthritis without Osteomyelitis (20 Patients) [4,447,450,457,709–711] | Osteomyelitis (45 Patients) [4,439–444,447,448,451,454–456,712–715] |
|---|---|---|
| Mean age at diagnosis (range) | 20 days (5-37) | 31 days (8-60) |
| Mean duration of symptoms (range) | 1.5 days (<1-3) | 9 days (1-28) |

## CELLULITIS OR ADENITIS

The manifestation of late-onset group B streptococcal infection designated as facial cellulitis [458], submandibular cellulitis [459], cellulitis/adenitis syndrome [460], or lymphadenitis [461] has been reported in at least 25 infants [462–465]. Presenting signs include poor feeding; irritability; fever; and unilateral facial, preauricular, or submandibular swelling, usually, but not always, accompanied by erythema. The mean age at onset is 5 weeks (range 2 to 11 weeks), and in contrast to all other expressions of late-onset infection, there is a striking male predominance (72%). The most common sites are the submandibular and parotid, and enlarged adjacent nodes become palpable within 2 days after onset of the soft

*References [4,439,440,444,447,448,456,457].

**FIGURE 12–8** Radiograph shows lytic lesion (*arrow*) of the proximal humerus in an infant whose bone biopsy showed osteomyelitis caused by type III group B streptococci.

tissue infection. Four of the five infants with facial or submandibular cellulitis described by Baker [460] had ipsilateral otitis media at the time of diagnosis. Less common sites of involvement with cellulitis are the face, preauricular or inguinal areas, scrotum, anterior neck region, and prepatellar spaces (Fig. 12–9) [460,464,465]. In one patient, cellulitis of the neck occurred in association with an infected thyroglossal duct cyst [460].

Bacteremia almost always is detected in these infants (92%), and cultures of soft tissue or lymph node aspirates have yielded GBS in 83% of the infants in whom this procedure was performed. These infants usually are not seriously ill, few have associated meningitis, and recovery within a few days of initiation of appropriate antimicrobial therapy is the rule. Fulminant and fatal facial cellulitis has been described in a 7-hour-old neonate [4], however, and associated meningitis has been described in two infants [466].

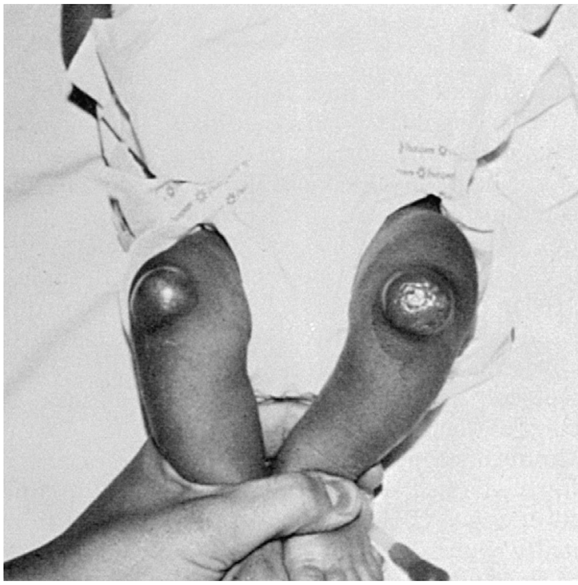

**FIGURE 12–9 Prepatellar bursitis of both knees in an infant who had abraded his knees on the bed sheets.** Aspiration of purulent material from the prepatellar space yielded type III group B streptococci. The knee joints were not affected.

## UNUSUAL MANIFESTATIONS OF INFECTION

Numerous uncommon clinical manifestations of early-onset and late-onset group B streptococcal infection have been recorded (Table 12–6). Peritonitis [467] and adrenal abscess [468–470] have been described as abdominal manifestations of early-onset and late-onset infection. Adrenal abscess is thought to result from bacteremic seeding associated with adrenal hemorrhage and subsequent abscess formation. One neonate thought to have neuroblastoma underwent en bloc resection of a large mass with nephrectomy before the diagnosis of adrenal abscess was established [469]. Gallbladder distention is a nonspecific manifestation of early-onset sepsis that usually resolves with medical management of the infection [471]. Late-onset bacteremia can occur in association with jaundice, elevated levels of liver enzymes, and increased direct-reacting bilirubin fraction. Hemolysis and hepatocellular inflammation possibly contribute to the development of jaundice.

Brain abscess rarely occurs in association with recurrence of group B streptococcal meningitis. One infant recovered after craniotomy and excision of a well-encapsulated frontal mass, but had neurologic sequelae [472]. Sokol and colleagues [473] described a 5-week-old infant with a cerebellar cyst believed to represent an astrocytoma. This infant proved to have obstructive hydrocephalus and chronic group B streptococcal ventriculitis. Rarely, anterior fontanelle herniation can complicate severe meningitis. The presence of a noncystic doughy mass over the fontanelle indicates that brain herniation may have occurred, and cranial ultrasonography or computed tomography (CT) can be obtained to confirm this diagnosis. One patient with cervical myelopathy initially had absence of extremity movement, but made a good recovery and was able to walk at age 3 years [474].

Another unusual complication of group B streptococcal meningitis is subdural empyema, which has been

**TABLE 12–6** Unusual Clinical Manifestations of Group B Streptococcal Infections

| Site and Manifestation | Associated with Early-Onset or Late-Onset Infection | Reference No. |
|---|---|---|
| Abdomen | | |

| Retropharyngeal cellulitis | Late | 507,508 |
| Scalp abscess | Both | 505 |
| Urinary tract infection | Both | 435,510 |

described in patients with early-onset and late-onset infections [475,476]. The diagnosis was established by needle aspiration of the subdural space at the time of hospital admission [476] or within the first 5 days of treatment. Irritability, vomiting, seizures, increasing head circumference, focal neurologic signs, a tense anterior fontanelle, or a combination of these prompted evaluation [475,477]. Sterilization of the subdural space was accomplished by open or closed drainage in conjunction with antimicrobial therapy. Basal ganglia and massive cerebral infarction also have been described [478].

Cardiovascular manifestations of group B streptococcal infection are rare. Endocarditis [136,449,479,480], pericarditis [481], myocarditis [456], and mycotic aneurysm of the aorta [482] have been documented. Echocardiography can be useful in delineating the nature of cardiac involvement, and this technique was employed successfully to detect a 0.7-cm vegetation on the anterior leaflet of the mitral valve in a 4-week-old infant with endocarditis caused by a type III strain [449]. Paroxysmal atrial tachycardia can be a presenting feature of group B streptococcal septicemia in the absence of focal infection of the heart [133].

GBS are an uncommon cause of otitis media in the first few weeks of life (2% to 3% of cases) [483]. Otitis media is more often associated with late-onset disease manifesting as meningitis or submandibular cellulitis [484–486]. The finding of acute mastoiditis at autopsy in one infant with otitis media and meningitis suggests that the middle ear can serve as a portal of entry in a few patients [486].

Conjunctivitis related to GBS occurs with such rarity that no cases were identified among 302 neonates with ophthalmia neonatorum described by Armstrong and associates [487]. Exudative conjunctivitis has been reported, however, in association with early-onset bacteremia [487]. More severe ocular involvement is rare, but endophthalmitis has been noted in infants with septicemia and meningitis [488]. As is the case for other agents producing endophthalmitis, high-grade bacteremia is a likely prelude to this unusual metastatic focus of group B streptococcal infection.

Supraglottitis was described in a 3-month-old infant with acute onset of stridor [489]. Swelling of the left aryepiglottic fold, but not the epiglottis, was noted at laryngoscopy. An infant with bacterial tracheitis had a similar presentation [490]. Although pulmonary infection caused by GBS is common, pleural involvement is rare, but it has been reported as a complication of early-onset [491] and late-onset [492] pneumonia. An interesting but unexplained association is delayed development of right-sided diaphragmatic hernia and early-onset group B streptococcal sepsis [493]. In affected infants, the onset of respiratory distress invariably occurs at or within 48 hours after birth, whereas the mean age at diagnosis of right-sided diaphragmatic hernia in the 40 reported cases is 11 days (range 4 to 91 days). One speculation is that group B streptococcal pneumonia causes necrosis of the adjacent diaphragm and results in herniation of viscera into the pleural space. Another is that ventilation increases intrathoracic pressure to mask or delay herniation through a congenital diaphragmatic defect. This phenomenon should be a consideration in an infant whose condition

deteriorates despite appropriate management for early-onset disease. Radiographic features include increased density in the right lower lung or irregular aeration or both, followed by progression to elevation of right bowel gas and liver shadow.

In addition to cellulitis and adenitis, GBS uncommonly can produce various unusual skin and soft tissue manifestations, including violaceous cellulitis [494], perineal cellulitis and septicemia after circumcision [495], scrotal ecchymosis as a sign of intraperitoneal hemorrhage [496], purpura fulminans [497,498], necrotizing fasciitis [499–501], impetigo neonatorum [502,503], omphalitis [421,504], scalp abscess secondary to fetal scalp electrode [505], abscess complicating cystic hygroma [506], retropharyngeal cellulitis [507,508], and breast abscess [509]. In patients with impetiginous lesions and abscess formation, bacteremia is unusual, but it is a frequent accompaniment to omphalitis and necrotizing fasciitis.

Among infants with early-onset bacteremia, isolation of GBS from the urine is frequent when this body fluid is cultured, but primary urinary tract infection with these organisms is rare. An infant with severe bilateral ureterohydronephrosis and GBS in his urine has been described [510]. The isolation of GBS from a urine culture of a patient without bacteremia is an indication for evaluation for possible structural anomalies of the genitourinary tract.

Sudden death occurred in three infants ranging from 3 to 8 months of age. The deaths were attributed at the time of autopsy to group B streptococcal infection [409].

## RELAPSE OR RECURRENCE OF INFECTION

Relapse or recurrence of group B streptococcal infection occurs in an estimated 0.5% to 3% of infants. Signs can develop during treatment for the initial episode or at an interval of 3 days to 3 months after completion of therapy [511–513]. In one review, eight of nine infants with a recurrence were born at 25 to 36 weeks of gestation, and male infants predominated [512]. The first episode occurred at a mean age of 10 days (range 1 to 27 days) and the recurrence at a mean age of 42 days (range 23 to 68 days) of life. In another report that included a set of fraternal twins, seven of eight infants were preterm (mean 30 weeks of gestation), each had a birth weight of less than 2500 g, and all infections were late-onset [513]. The mean age at initial presentation was 38 days (range 13 to 112 days), and at recurrence it was 57 days (range 34 to 130 days). Two relapses in one infant have been documented [514,515].

Relapse or recurrence of infection can be the result of an undrained focus of infection, such as a brain abscess, or can occur in association with congenital heart disease. Identical isolates recovered from maternal genital and breast milk cultures suggest that breast milk can serve as a source of repeated infant exposure [516,517]. Recurrent infection can have a clinical expression similar to that of the initial episode or can involve new sites (meninges, ventricular or subdural fluid, or both; brain parenchyma; and soft tissue). In most instances, the second episode of group B streptococcal disease responds to retreatment with penicillin or ampicillin, but typically the duration of treatment for the recurrence is extended empirically; evidence for longer duration of therapy in this circumstance is lacking [513].

Because infants who receive treatment for invasive infection often remain colonized with GBS at mucous membrane sites, pharyngeal or gastrointestinal colonization can be the source for recurrence. In addition, infants recovering from invasive infection with type III strains usually lack protective levels of antibody during convalescence. Moylett and colleagues [513] and others [514] used pulsed-field gel electrophoresis to document that isolates from patients with recurrent episodes were identical and were derived from a single clone. Sets of isolates analyzed from first and second episodes and from maternal and infant colonizing and invasive strains were genotypically identical [512,513]. Recurrent infection in most infants likely is a consequence of reinvasion from persistently colonized mucous membrane sites or from reexposure to a household carrier. The timing of the recurrence or relapse in Moylett's series was 4 days after discontinuation of appropriate therapy. Uncommonly, infants have had a second infection with a strain that is genetically unrelated to the original isolate.

## MATERNAL INFECTIONS

In 1938, Fry [1] described three fatal cases of endocarditis in postpartum women. This was the initial insight that group B *Streptococcus* was a human pathogen and could cause puerperal infection. Postpartum infections including septic abortion, bacteremia, chorioamnionitis, endometritis, pneumonia, and septic arthritis were recorded sporadically thereafter, but group B streptococcal infections in postpartum women, as in neonates, were uncommonly reported before 1970 [413,518,519]. The dramatic increase in incidence of neonatal infections in the 1970s was paralleled by an increased incidence of infections in pregnant women.

Before the institution of Intrapartum Antibiotic Prophylaxis in the 1990s, GBS accounted for 10% to 20% of blood culture isolates from febrile women on obstetric services [520]. These women had a clinical picture characterized by fever, malaise, uterine tenderness with normal lochia, and occasionally chills. Faro [334] described 40 women with group B streptococcal endometritis and endoparametritis among 3106 women giving birth over a 12-month interval, an incidence of 1.3 per 1000 deliveries. GBS were isolated from the endometrium in pure culture in one third of cases or in addition to other organisms in the remainder; one third of the women had concomitant bacteremia. In most, signs of infection developed within the first 24 hours after cesarean section. Clinical features included chills; tachycardia; abdominal distention; and exquisite uterine, parametrial, or adnexal tenderness. Higher fever correlated with risk for concomitant bacteremia. Recovery was uniform after administration of appropriate antimicrobial agents. Six infants born to these women developed group B streptococcal septicemia, however, and infection was fatal was three. The observation that maternal febrile morbidity could serve as an early clue to bacteremic neonatal infection is important, and infants of such women should be carefully evaluated.

The contemporary incidence of invasive disease in pregnant women is 0.12 per 1000 live births [150]. This incidence has declined significantly in association with implementation of IAP to prevent early-onset neonatal disease [12,143]. Half of the 409 pregnancy-associated disease cases identified in the United States from 1999-2005 by an active population-based surveillance system were associated with infection of the upper genital tract, placenta, or amniotic sac and resulted in fetal death. Among the remainder, manifestations of disease included bacteremia without a focus (31%), endometritis without fetal death (8%), chorioamnionitis without fetal death (4%), pneumonia (2%), and puerperal sepsis (2%). Isolates in pregnancy-associated infections were obtained from blood in 52% of women and from the placenta, amniotic fluid, or conceptus in most of the remainder. When pregnancy outcome was known, most of the women (61%) had a spontaneous abortion or stillborn infant, 5% had infants who developed clinical infection, 4% had induced abortions, and 30% had infants who remained clinically well [150].

Most obstetric patients with group B streptococcal infection, even in the presence of bacteremia, show a rapid response after initiation of antimicrobial therapy. Potentially fatal complications can occur, however, including meningitis [521], ventriculoperitoneal shunt infection [522], abdominal abscess [523], endocarditis [142,524–526], vertebral osteomyelitis [527], epidural abscess [528], or necrotizing fasciitis [529].

Group B streptococcal bacteriuria during pregnancy is a risk factor for intrauterine or neonatal infection. Asymptomatic bacteriuria, cystitis, or pyelonephritis occurs in 6% to 8% of women during pregnancy. In women with asymptomatic bacteriuria, approximately 20% are caused by GBS [530]. Group B streptococcal bacteriuria is a marker for heavy vaginal colonization, so the finding of bacteriuria indicates enhanced risk for maternal and neonatal infection [100]. In the series reported by Moller and associates [414] that predated IAP, a cohort of 68 women with asymptomatic group B streptococcal bacteriuria had significantly increased risk of preterm delivery compared with nonbacteriuric controls. Stillbirth because of congenital group B streptococcal infection can occur even in the current era, and a woman with any quantity of group B streptococcal bacteriuria during pregnancy should receive IAP [531].

# DIAGNOSIS

## ISOLATION AND IDENTIFICATION OF THE ORGANISM

The definitive diagnosis of invasive group B streptococcal infection is established by isolation of the organism from culture of blood, CSF, or a site of suppurative focus (e.g., bone, joint fluid, empyema fluid). Isolation of GBS from surfaces, such as the skin or umbilicus or from mucous membranes, is of no clinical significance.

Lumbar puncture is required to exclude meningeal involvement in infants with invasive group B streptococcal infection because clinical features cannot reliably distinguish between meningeal and nonmeningeal involvement. GBS often are isolated from blood at the time of initial evaluation of infants with meningitis, but the blood culture is sterile in 20% to 30%. Wiswell and colleagues [532] found that if lumbar puncture were omitted as part of the sepsis evaluation, the diagnosis of meningitis was missed or delayed in more than one third of infants. Infants with late-onset infection can have meningitis even when focal infection, such as cellulitis, is apparent [466]. If lumbar puncture must be deferred because an infant is clinically unstable, penicillin G or ampicillin at the doses recommended for treatment of group B streptococcal meningitis (see “Treatment” later on) should be administered until meningeal involvement can be assessed.

### Antigen Detection Methods

Antigen detection is not a substitute for appropriately performed bacterial cultures and now is rarely used to establish a provisional diagnosis of group B streptococcal infection. A positive result indicates that group B streptococcal antigen is detectable, but not that viable organisms are present. Serum and CSF are the only specimens recommended for testing [533]. In neonates with meningitis, the sensitivity of antigen detection is 72% to 89%. The estimated sensitivity for serum is 30% to 40%. False-positive results have been encountered. The estimated specificity of commercial assays ranges from 95% to 98%. Antigen assays should not be employed to assess treatment efficacy.

Real time RT-PCR has been evaluated in a research setting to assess group B streptococcal exposure in infants born to women whose colonization status is unknown at delivery. The rates of colonization detected by culture and PCR were 17% and 51%. The authors suggest that a negative PCR test could be useful in allowing early discharge of infants born to mothers with a negative real time RT-PCR [534]. A fluorescent real time RT-PCR assay was shown to be sensitive and specific for early detection within 4 hours of incubation of GBS in neonatal blood cultures, but at the present time this test is not available commercially [535].

### Other Laboratory Tests

Acute-phase reactants, such as C-reactive protein, can be elevated during group B streptococcal infection, but the usefulness for establishing a provisional diagnosis of infection is limited. The return to normal of the C-reactive protein level could be helpful, however, in minimizing antibiotic exposure in the nursery setting [536]. Levels of inflammatory cytokines such as IL-6 are elevated acutely during group B streptococcal sepsis. In one report, production of IL-6 was noted in all 16 neonates with bacteremic early-onset or late-onset group B streptococcal infection when samples were collected within 48 hours of initiation of antimicrobial therapy [537]. These assays generally are not available in clinical laboratories, however.

Abnormalities in the white blood cell count, including leukopenia, neutropenia, leukocytosis, increase in band forms, or decline in the total white blood cell count in the first 24 hours of life, can be suggestive of group B streptococcal infection. Greenberg and Yoder [538] cautioned that repeat testing at 12 to 24 hours of age can enhance sensitivity compared with testing at 1 to 7 hours

of age. Fatal early-onset group B streptococcal sepsis can occur with a normal leukocyte count, however [539]. Measurements of peripheral blood leukocytes or inflammatory mediators generally are nonspecific and should be employed only as adjunctive to results from blood and CSF cultures.

## DIFFERENTIAL DIAGNOSIS

The clinical features in neonates with early-onset group B streptococcal infection mimic the features in infants with sepsis caused by other etiologic agents and by some noninfectious illnesses. Radiographic findings of pneumonia are present in some neonates with early-onset group B streptococcal sepsis. Neonates with early-onset group B streptococcal pneumonia can have apnea and shock within the first 24 hours of life, a 1-minute Apgar score of 5 or less, and an unusually rapid progression of pulmonary disease [208]. Infection also should be considered in neonates with persistent fetal circulation associated with respiratory distress, neutropenia, and systemic hypotension [212].

The differential diagnosis for late-onset group B streptococcal infection depends on the clinical presentation. For infants with meningitis, the characteristic CSF Gram stain findings can provide a presumptive diagnosis. When this method is inconclusive usually in the setting of partial treatment, other organisms, including viruses, *E. coli*, *Neisseria meningitidis*, *S. pneumoniae*, and nontypable *Haemophilus influenzae*, must be considered. Fever usually is a presenting feature in term infants, and empirical therapy with broad-spectrum antibiotics customarily is employed until results of cultures permitting a specific diagnosis of bacteremia or focal infection are available. The paucity of signs characteristic of group B streptococcal osteomyelitis and the history that signs have been present since birth have caused confusion with Erb palsy and neuromuscular disorders. The characteristic bony lesion; tenderness of the extremity when a careful examination is performed; and isolation of the organism from blood, bone, or joint fluid usually provide a definitive diagnosis [439]. Finally, the lengthy list of uncommon manifestations of infection between 1 week and 3 months of age and beyond indicates that GBS should be suspected as an etiologic agent, regardless of site of infection, for infants in this age group.

# TREATMENT

GBS have been a frequent cause of infection in neonates for 4 decades, resulting in increased awareness of associated risk factors and need for prompt and aggressive therapy. Despite striking declines, however, death and disability from these infections still occur. In addition, relapses or reinfections, although uncommon, occur in the face of optimal therapy. These facts should prompt efforts to develop improved treatment modalities.

## IN VITRO SUSCEPTIBILITY

Uniform susceptibility of GBS to penicillin G has continued for more than 50 years of usage [540–545]. More recently, reduced susceptibility of certain strains of GBS to penicillin and other β-lactam antibiotics has been documented in the United States [546] and Japan [547] and experimentally traced to point mutations in penicillin-binding proteins reminiscent of first-step mutations in the evolution of pneumococcal penicillin resistance decades ago. The clinical implications of this finding are as yet unclear. Efforts should be continued, however, to monitor clinical isolates for mutations that would suggest the evolution of penicillin-resistant strains. In vitro susceptibility of GBS to ampicillin, semisynthetic penicillins, vancomycin, teicoplanin, linezolid, quinopristin/dalfopristin, gatifloxacin, levofloxacin, and first-generation, second-generation (excluding cefoxitin), and third-generation cephalosporins also is the rule, although the degree of in vitro activity varies [543,544,548–554]. Ceftriaxone is the most active of the cephalosporins in vitro. Imipenem and meropenem are highly active [541,548]. Resistance to quinolones can occur through mutations in the gyrase and topoisomerase IV genes, usually in patients who have received prior quinolone therapy [555].

Resistance to erythromycin and clindamycin is increasing. Contemporary data from multiple studies indicate that 20% to 30% of isolates are erythromycin-resistant, and 10% to 20% are resistant to clindamycin [543,544,556]. Rates of resistance in colonizing isolates can be 40% for erythromycin and clindamycin [557]. These high rates of resistance are reported from geographically diverse regions [558–561].

Macrolide resistance mechanisms include ribosomal modification by a methylase encoded by *erm* genes and drug efflux by a membrane-bound protein encoded by *mef* gene [556]. The presence of *erm* genes results in the macrolide–lincosamide–streptogramin B resistance phenotype [562]. Erythromycin-resistant isolates that are constitutively resistant, inducibly resistant, or susceptible to clindamycin are described [563]. Alone or in combination, *erm*(A), *erm*(B), and *mef*(A) genes are responsible for resistance in GBS. An *erm*(T) gene has been identified in a few strains of GBS inducibly resistant to clindamycin [564]. The presence of a composite transposon in GBS and pneumococci suggests that *erm*(B)-mediated macrolide resistance could be due to the horizontal transfer of a mobile transposable element [565]. A particularly high proportion of strains resistant to erythromycin has been reported for type V [544,566]. Tigecycline and telithromycin are active in vitro against macrolide-resistant GBS, but data confirming their clinical effectiveness are scant [567,568]. The percentage of tetracycline-resistant strains is 75% to nearly 90% [549]. Resistance of GBS to bacitracin, nalidixic acid, trimethoprim-sulfamethoxazole, metronidazole, and aminoglycosides is uniform.

Despite resistance of most group B streptococcal strains to aminoglycosides, synergy often is observed when an aminoglycoside (especially gentamicin) and penicillin or ampicillin are used in combination [553,569]. The best combination theoretically to accelerate the killing of GBS in vivo is penicillin or ampicillin plus gentamicin. Therapeutic concentrations of gentamicin in the serum are not required to achieve synergy. By contrast, the rapid and predictable bactericidal effect of penicillin or ampicillin on GBS in vitro is ablated by the addition

of rifampin [570]. Although in vivo data are lacking, the in vitro antagonism of rifampin when combined with penicillins suggests that they should not be employed concurrently in the treatment of proven or suspected group B streptococcal disease.

Among the newer β-lactam antibiotics reputed to attain high concentrations of drug in the CSF, only cefotaxime, ceftriaxone, meropenem, and imipenem achieve minimal bactericidal concentrations (MBCs) comparable with MBCs of penicillin G and ampicillin (0.01 to 0.4 μg/mL) [541,549,553,556], and limited data suggest that their efficacy is equivalent to that of penicillin G [553,571,572]. Despite their uniform susceptibility to penicillin G, GBS require higher concentrations for growth inhibition in vitro than strains belonging to group A. The minimal inhibitory concentration (MIC) of penicillin G to GBS is 4-fold to 10-fold greater than the MIC for group A strains (range 0.003 to 0.4 μg/mL) [540,549,573]. This observation, combined with the observation indicating the significant influence of inoculum size on in vitro susceptibility to penicillin G, may have clinical relevance [540,574].

When the inoculum of group B *Streptococcus* is reduced from $10^5$ to $10^4$ colony-forming units (CFU)/mL, a twofold lower concentration of penicillin G is sufficient to inhibit in vitro growth. Similarly, if the inoculum is increased from $10^4$ to $10^7$ CFU/mL, the MBC of ampicillin is increased from 0.06 to 3.9 μg/mL. Such in vitro observations may have in vivo correlates because some infants with group B streptococcal meningitis have CSF bacterial concentrations of $10^7$ to $10^8$ CFU/mL [574]. At the initiation of therapy for meningitis, achievable CSF levels of penicillin G or ampicillin may be only one tenth of serum levels. This inoculum effect also has been noted with cefotaxime and imipenem [549]. The dose chosen to treat group B streptococcal meningitis can be crucial to the prompt sterilization of CSF.

Although GBS are susceptible to penicillin G, in vitro tolerance among 4% to 6% of strains has been noted [575]. Defined as MBC in excess of 16 to 32 times the MIC, tolerance in vitro corresponds with delayed bacterial killing, additive rather than synergistic effects when gentamicin is used in combination with penicillin G, and possibly an autolytic enzyme defect in such strains [576]. Detection of tolerance depends, however, on choice of growth medium, growth phase of bacterial inoculum, and definition of MBC employed for testing.

## ANTIMICROBIAL THERAPY

Penicillin G is the drug of choice for treatment of group B streptococcal infections. The recommended dosage for treatment of meningitis is high because of (1) the relatively high MIC of penicillin G for GBS (median 0.06 μg/mL) with respect to attainable levels of this drug in the CSF, (2) the high inoculum in the CSF of some infants [574], (3) reports of relapse in infants with meningitis treated for 14 days with 200,000 U/kg/day of penicillin G, and (4) the safety of high doses of penicillin G in the newborn. To ensure rapid bactericidal effects, particularly in the CSF, we recommend penicillin G (450,000 to 500,000 U/kg/day) or ampicillin (300 to 400 mg/kg/day) for the treatment of meningitis (Table 12–7). There is no evidence to suggest increased risk for adverse reactions at these higher doses even in premature infants.

In the usual clinical setting, antimicrobial therapy is initiated before definitive identification of the organism. Initial therapy should include ampicillin and an aminoglycoside appropriate for the treatment of early-onset neonatal pathogens including GBS. Such a combination is more effective than penicillin G or ampicillin alone for killing of GBS [569,573]. We continue combination therapy until the isolate has been identified as GBS and, in patients with meningitis, until a CSF specimen obtained 24 to 48 hours into therapy is sterile. Kim [576] suggests that MIC and MBC determinations be considered in the following settings: (1) a poor bacteriologic response to antimicrobial therapy, (2) relapse or recurrence of infection without a discernible cause, and (3) infections manifested as meningitis or endocarditis. If tolerance is shown, therapeutic choices include using penicillin G or ampicillin alone or employing cefotaxime. No data are available to indicate the better of these choices [577].

For an infant with late-onset disease in whom CSF reveals gram-positive cocci in pairs or short chains, initial therapy should include ampicillin and gentamicin or

**TABLE 12–7** Antimicrobial Regimens Recommended for Treatment of Group B Streptococcal Infections in Infants*

| Manifestation of Infection | Drug | Daily Dose (Intravenous) | Duration |
|---|---|---|---|
| Bacteremia without meningitis | Ampicillin plus gentamicin | 150-200 mg/kg plus 7.5 mg/kg | Initial treatment before culture results (48-72 hr) |
| | Penicillin G | 200,000 U/kg | Complete a total treatment course of 10 days |
| Meningitis | Ampicillin plus gentamicin | 300-400 mg/kg plus 7.5 mg/kg | Initial treatment (until cerebrospinal fluid is sterile) |
| | Penicillin G | 500,000 U/kg | Complete a minimum total treatment course of 14 days† |
| Septic arthritis | Penicillin G | 200,000 U/kg | 2-3 wk |
| Osteomyelitis | Penicillin G | 200,000 U/kg | 3-4 wk |
| Endocarditis | Penicillin G | 400,000 U/kg | 4 wk‡ |

**No modification of dose by postnatal age is recommended. Oral therapy is never indicated.*
*†Longer treatment (up to 4 wk) may be required for ventriculitis.*
*‡In combination with gentamicin for the first 14 days.*

ampicillin and cefotaxime, rather than penicillin G alone, because (1) GBS are a frequent cause of meningitis in infants 1 to 8 weeks of age, and combination therapy can improve efficacy early in the course of infection, and (2) *Listeria monocytogenes* can be confused by CSF Gram stain with group B *Streptococcus*, and ampicillin and gentamicin are synergistic in vitro against most strains of *Listeria*. If pneumococcal meningitis is a consideration, cefotaxime and vancomycin would be a reasonable empirical regimen pending culture confirmation. Because group B streptococcal meningitis is uncommon beyond 8 weeks of age, no change is suggested from the use of conventional agents as the initial treatment of meningitis in term infants older than 2 months. For preterm infants remaining hospitalized from birth, empirical therapy can include vancomycin and an aminoglycoside. If meningitis is suspected, ampicillin or cefotaxime should be included in the regimen because vancomycin achieves low CSF concentrations and has a substantially higher MBC against GBS and *L. monocytogenes* than ampicillin.

When the diagnosis of group B streptococcal infection is confirmed, and CSF for patients with meningitis obtained 24 to 48 hours into therapy is sterile, treatment can be completed with penicillin G monotherapy. Good outcomes have been achieved when parenteral therapy is given for 10 days for bacteremia without a focus or with most soft tissue infections, 2 to 3 weeks for meningitis or pyarthrosis, and 3 to 4 weeks for osteomyelitis or endocarditis (see Table 12–7). Limited evidence suggests that a 7-day course of therapy can suffice for uncomplicated bacteremia, but additional data would be required to support a change in current recommendations [578]. For infants with meningitis, failure to achieve CSF sterility suggests an unsuspected suppurative focus (subdural empyema, brain abscess, obstructive ventriculitis, septic thrombophlebitis) or failure to administer an appropriate drug in sufficient dosage.

At the completion of therapy (minimum 14 days), a lumbar puncture should be considered to evaluate whether the CSF findings are compatible with resolution of the inflammatory process or are of sufficient concern to warrant extending treatment or additional diagnostic evaluation. Neutrophils greater than 30% of the total cells or a protein concentration greater than 200 mg/dL warrants consideration for a neuroimaging study of the brain. These findings can be observed in patients with a fulminant course manifested by severe cerebritis, extensive parenchymal destruction with focal suppuration, or severe vasculitis with cerebral infarctions.

Infants with septic arthritis should receive at least 2 weeks of parenteral therapy; infants with bone involvement require 3 to 4 weeks of therapy to optimize an uncomplicated outcome. Drainage of the suppurative focus is an adjunct to antibiotic therapy. In infants with septic arthritis excluding the hip or shoulder, one-time needle aspiration of the involved joint usually achieves adequate drainage. With hip or shoulder involvement, immediate open drainage is warranted. For most infants with osteomyelitis, some type of closed or open drainage procedure is required for diagnosis because blood cultures typically are sterile. These procedures must be performed before or early in the course of therapy to ensure successful isolation of the infecting organism.

With recurrent infection, three points should be considered. First, appropriate antimicrobial therapy fails to eliminate mucous membrane colonization with GBS in 50% of infants [579]. Second, community exposure can result in colonization with a new strain that subsequently invades the bloodstream. Systemic infection in neonates does *not* result in protective levels of CPS type–specific antibodies [341]. Recurrent infections do occur in healthy infants. In this event, an evaluation to exclude an immune abnormality, such as HIV infection or hypogammaglobulinemia, can be considered, but detection of abnormalities is rare. Therapy for recurrent infection need not be extended beyond that appropriate to the clinical expression of the recurrent infection. Finally, although it is desirable to eliminate colonization, an efficacious regimen has not been identified. One small prospective study revealed that administration of oral rifampin (20 mg/kg/day for 4 days) to infants after completion of parenteral therapy eliminated mucous membrane colonization in some subjects [580]. Further study is needed to identify a more reliable approach to eliminating colonization.

## SUPPORTIVE MANAGEMENT

Prompt, vigorous, and careful supportive care is important to the successful outcome of most group B streptococcal infections. When early-onset disease is accompanied by respiratory distress, the need for ventilatory assistance should be anticipated before onset of apnea. Early treatment of shock, often not suspected during its initial phase, when systolic pressure is maintained by peripheral vasoconstriction, is crucial. Persistent metabolic acidosis and reasonably normal color are characteristic of this early phase. Persistent perfusion abnormalities after initial attempts to achieve adequate volume expansion warrant placement of a central venous pressure monitoring device and treatment with appropriate inotropic agents. This concept applies also to patients with late-onset meningitis. Fluid management should include packed red blood cell transfusions to optimize oxygen-carrying capacity. In patients with meningitis, effective seizure control is required to achieve proper oxygenation, to decrease metabolic demands, prevent additional cerebral edema, and optimize cerebral blood flow. Monitoring of urine output and attention to electrolyte balance and osmolality are needed to detect and manage the early complications of meningitis, such as inappropriate secretion of antidiuretic hormone and increased intracranial pressure. Such intense and careful supportive management requires treatment in an intensive care unit of a tertiary care facility.

Extracorporeal membrane oxygenation (ECMO) has been suggested as rescue therapy for overwhelming early-onset group B streptococcal sepsis. Hocker and coworkers [581] compared conventional treatment with ECMO for neonates with early-onset disease. Survival was not improved significantly with use of ECMO when all infants or only hypotensive infants were compared. LeBlanc [582] emphasized the difficulty of interpreting this study, citing the retrospective design and the fact that the sickest infants die before ECMO can be initiated. Until a prospective, controlled trial is performed, ECMO therapy should be considered controversial.

## ADJUNCTIVE THERAPIES

Despite prompt initiation of antimicrobial therapy and aggressive supportive care, death or sequelae can result from group B streptococcal infection. Considerable investigative efforts have been directed toward adjunctive therapy. High mortality rates for neutropenic neonates prompted clinical evaluation of granulocyte transfusions as adjunctive therapy for early-onset group B streptococcal sepsis. In three trials, 13 infants with neutrophil storage pool depletion were assessed [278,378,583]. The results seemed promising, but the logistics of providing timely transfusion and the concern for adverse effects, such as graft-versus-host reaction, transmission of viral agents, and pulmonary leukocyte sequestration, render this approach to therapy impractical.

Recombinant human cytokine molecules such as granulocyte colony-stimulating factor promote granulocyte proliferation, enhance chemotactic activity and superoxide anion production, and increase expression of neutrophil C3bi receptors. Results in experimental infection suggest that granulocyte colony-stimulating factor might be a useful adjunct in the treatment of group B streptococcal neonatal sepsis, possibly in combination with intravenous immunoglobulin (IVIG) [584–586]. Specific recommendations must await evaluation of their safety and efficacy in controlled clinical trials.

Human immunoglobulin modified for intravenous use could provide specific antibodies to enhance opsonization and phagocytosis of GBS [587–593]. IVIG has been shown in experimental models [594] and septic neonates [595] to improve complement activation and chemotaxis by neonatal sera and to hasten resolution of neutropenia. Administration of sufficient human type-specific antibodies against CPS to animals before lethal challenge with GBS of the homologous serotype is protective [350,587–591]. Despite this sound theoretical rationale, commercial preparations of IVIG contain relatively low concentrations of antibodies to group B streptococcal polysaccharides [590–593,595–600], suggesting that prohibitively large doses would be required and raising concern for reticuloendothelial blockade [589,592]. In addition, functional activity of licensed IVIG preparations can vary by manufacturer and lot [588,589,595–601], and any increase in antibodies after infusion would be transient only [596,602]. Christensen and colleagues [603] administered either IVIG (750 mg/kg) or albumin to 22 neonates with severe, early-onset sepsis, however, and all infants survived. Eleven patients had neutropenia, but in IVIG recipients, this abnormality resolved within 24 hours of infusion, whereas it persisted in placebo recipients.

A hyperimmune group B streptococcal globulin or human-human monoclonal antibodies would theoretically circumvent many potential problems. Raff and coworkers [604] developed a human IgM monoclonal antibody specific for the group B cell wall polysaccharide. This antibody reacted with all group B streptococcal types tested and was shown to be safe and protective in newborn, nonhuman primates [605]. A hyperimmune globulin [599] prepared by vaccinating healthy adults with polysaccharides from types Ia, Ib, II, and III GBS was protective against experimental challenge with types I, II, and III strains [606]. To date, no commercial preparation of IVIG hyperimmune for IgG directed against type-specific CPS is available, however, for testing in appropriately designed clinical trials.

## PROGNOSIS

Several clinical scoring systems have been developed to predict at the time of initial evaluation infants likely to die as a consequence of neonatal group B streptococcal infection [212,432,607]. Payne and colleagues [212] described a score derived from five variables that, together with an initial blood pH less than 7.25, enabled prediction of outcome accurately in 93% of infants with early-onset group B streptococcal infection. These features were birth weight less than 2500 g, absolute neutrophil count less than 1500 cells/mm$^3$, hypotension, apnea, and pleural effusion seen on the initial chest radiograph.

A fatal outcome can be predicted with reasonable accuracy, but little information is available concerning the long-term prognosis for survivors of neonatal group B streptococcal sepsis. One group at potential risk for sequelae are preterm infants with septic shock, who can develop periventricular leukomalacia. Among these survivors, substantial neurodevelopmental sequelae have been identified at evaluation during the second year of life. The correlates of severity and duration of shock with periventricular leukomalacia and with long-term morbidity from group B streptococcal disease have not been assessed. Prospective, active surveillance of neonatal group B streptococcal infections in Germany conducted from 2001-2003 found that 14% of 347 infants had neurologic sequelae of infection at the time of discharge from the hospital [608].

Long-term outcomes for survivors of group B streptococcal meningitis are guarded. Among 41 survivors from a cohort born in 1996-1997 in England and Wales, 34% had moderate or severe disability, 27% had mild disability, and 39% were functioning normally at 5 years of age [609]. Stoll and colleagues [610] showed for extremely low birth weight infants that meningitis with or without sepsis was associated with poor neurodevelopmental and growth outcomes and impairment of vision and hearing in early childhood.

Among 200 neonates with early-onset or late-onset meningitis cared for in the 1970s and 1980s, one quarter died in the hospital as the direct consequence of meningitis [429,431,432]. Among 112 survivors assessed at mean intervals 2 to 8 years after diagnosis, 20% had major neurologic sequelae. The most serious of these were profound mental retardation, spastic quadriplegia, cortical blindness, deafness, uncontrolled seizures, hydrocephalus, and hypothalamic dysfunction with poor thermal regulation and central diabetes insipidus [429,432,476,611]. Mild or moderate sequelae persisted in an additional 20% of survivors evaluated at a mean of 6 years after diagnosis. These sequelae included profound unilateral sensorineural hearing loss, borderline mental retardation, spastic or flaccid monoparesis, and expressive or receptive speech and language delay.

In a sibling-controlled follow-up study, 12% of survivors had major neurologic sequelae when evaluated at

3 to 18 years of age. When these nine children were excluded, there were no significant differences, as rated by parents, between the children with meningitis and their siblings for academic achievement, measures of intelligence quotient, fine motor dexterity, or behavior difficulties [611]. Meningitis survivors were more likely than siblings to have seizure disorders and hydrocephalus. More subtle deficits, such as delayed language development and mild hearing loss, may not be detected by routine examination [432], and meningitis survivors should undergo audiometric testing during convalescence and careful long-term neurologic and developmental assessments.

# PREVENTION

Theoretically, early-onset and late-onset group B streptococcal disease could be prevented if susceptible hosts were not exposed to the microorganism or if exposure occurred in the setting of protective immunity. Several approaches to prevention have been advocated; conceptually, these are directed at eliminating exposure or enhancing host resistance by chemoprophylaxis or immunoprophylaxis. Both strategies have limitations with respect to implementation, but could be targeted for the prevention of maternal and neonatal infections and are theoretically achievable [612,613].

## CHEMOPROPHYLAXIS

### Historical Precedents

Chemoprophylaxis was suggested as a means to prevent early-onset group B streptococcal infection by Franciosi and coworkers in 1973 [2]. Because maternal genital colonization was recognized to expose infants to the organism, oral penicillin treatment for colonized women was subsequently proposed. Carriers of GBS identified by third-trimester vaginal culture received a course of an oral antimicrobial. Approximately 20% to 30% remained colonized after treatment, and in most of these women, GBS were isolated from vaginal cultures at delivery [614–616]. Reacquisition from colonized sexual partners was suggested as an explanation for these high failure rates, but failure rates remained high when colonized pregnant women and their spouses received concurrent treatment with penicillin by the oral or the parenteral route [2,614,617]. One explanation cited for failure of this approach was the difficulty in eradicating a constituent of the normal bowel flora [614].

Yow and colleagues [618] gave intravenous ampicillin at hospital admission to 34 women in labor and vaginally colonized with GBS and successfully interrupted vertical transmission of colonization in all. Boyer and Gotoff [619,620] provided in 1986 the first documentation that IAP could prevent invasive early-onset neonatal infection. Women colonized with GBS who had risk factors for early-onset infection were randomly assigned to receive routine labor and delivery care or intrapartum ampicillin intravenously until delivery. Group B streptococcal sepsis developed in 5 of 79 neonates in the routine care group, 1 of whom died, whereas 85 infants born to women in the ampicillin treatment group remained well. Intrapartum ampicillin prophylaxis for group B streptococcal carriers also resulted in reduced maternal morbidity [621]. These data established the efficacy of IAP for prevention of early-onset neonatal disease and reduction of group B *Streptococcus*–associated febrile maternal morbidity. The cost-effectiveness of this approach subsequently was validated [622,623].

In 1992, the American College of Obstetricians and Gynecologists (ACOG) [624] and the American Academy of Pediatrics (AAP) [625] published separate documents regarding maternal IAP for the prevention of early-onset group B streptococcal infection. The ACOG technical bulletin was educational, whereas the AAP guidelines were directive. The AAP guidelines specified that if culture screening was performed antenatally, specimens should be obtained from lower vaginal and rectal sites, and culture-positive women with one or more risk factors and group B streptococcal colonization should be given intrapartum intravenous penicillin G or ampicillin. The ACOG proposed that culture screening could be avoided by providing treatment for all women with risk factors. Neither the AAP nor ACOG approach was implemented widely, and invasive disease rates remained unacceptably high.

### Rapid Assays for Antenatal Detection of Group B Streptococci

There are difficulties inherent to ascertainment of group B streptococcal colonization status rapidly even when assays can be processed 24 hours a day. Latex particle agglutination and enzyme immunoassays for detection of group B streptococcal antigen in cervical or lower vaginal swab specimens are not sufficiently sensitive to determine colonization status accurately at hospital admission, especially for women with a low density of organisms [626]. An optical immunoassay (Strep B OIA test; Biostar, Boulder, CO) was considerably more sensitive than earlier assays for detecting light (13% to 67%) and heavy (42% to 100%) or overall (81%) colonization and has outperformed enzyme immunoassays in direct comparisons [626–630]. Assays using a DNA hybridization methodology have shown variable sensitivity [631,632].

Bergeron and colleagues [633] described a fluorogenic real time RT-PCR technique for rapid identification of women colonized with GBS at admission for delivery. The sensitivity of real time RT-PCR and of conventional PCR was 97%, the negative predictive value was 99%, and the specificity and positive predictive value were 100%. Results were available from real time RT-PCR in 45 minutes; by comparison, conventional PCR required 100 minutes, and conventional cultures required 36 hours minimum. Field testing of commercially available assays such as the Xpert GBS Assay (Cepheid, Sunnyvale, CA) that uses automated rapid real time RT-PCR technology and IDI-StrepB (Infectio Diagnostic, Quebec, Canada) that uses a PCR assay to amplify group B streptococcal target has been conducted [634–636]. The performance of real time RT-PCR and optical immunoassay is sufficiently robust for use in point-of-care settings [637]. A cost-benefit analysis suggests that widespread implementation would afford benefit over the current culture-based strategy, but, to date, these newer methods should be considered as adjunctive tests to antenatal culture-based methods for detection of GBS [638].

## Intrapartum Antibiotic Prophylaxis

The current era of IAP dates from 1996, when consensus recommendations for the prevention of early-onset group B streptococcal disease were endorsed by the CDC, AAP, and ACOG [533,639,640]. These recommendations indicated that obstetric care providers and hospitals should adopt a culture-based or a risk-based policy to identify women to receive IAP. The culture-based approach employed lower vaginal and rectal cultures obtained at 35 to 37 weeks of gestation to identify candidates for IAP. The risk-based strategy identified IAP recipients by factors known to increase the likelihood of neonatal group B streptococcal disease: labor onset or membrane rupture before 37 weeks of gestation, intrapartum fever greater than or equal to 38° C (≥100.4° F), or rupture of membranes 18 or more hours before delivery. In both strategies, women with group B streptococcal bacteriuria or previous delivery of an infant with group B streptococcal disease were to receive IAP. These strategies each resulted in the administration of IAP to approximately one in four pregnant women [639].

The incidence of early-onset disease declined by 70% from 1.7 per 1000 live births to 0.5 per 1000 live births by 1999 in association with implementation of one of these two IAP methods (Fig. 12–10) [612,641]. A resulting 3900 to 4500 early-onset infections and 200 to 225 neonatal deaths were estimated to be prevented annually [612,642]. By contrast, the rate of late-onset disease remained constant at 0.5 to 0.6 per 1000 live births. Also, the incidence of invasive group B streptococcal disease, primarily bacteremia with or without intra-amniotic infection or endometritis among pregnant women declined significantly, from 0.29 per 1000 live births in 1993 to 0.23 in 1998 [612,642]. By 1999, two thirds of U.S. hospitals in a multistate survey had a formal prevention policy, and numerous individual practitioners had adopted one of the two strategies proposed in 1996 [612,643].

By 2002, it was evident that further reduction in the incidence of early-onset disease could be accomplished by adoption of universal culture screening. A direct comparison in 5144 births showed that the culture-based strategy was 50% more effective than the risk-based strategy in preventing early-onset disease in neonates [171]. Culture-based screening more often resulted in administration of IAP for at least 4 hours before delivery. The 2002 revised CDC guidelines recommending a universal culture-based approach to prevention of perinatal group B streptococcal disease are endorsed by the AAP and the ACOG [612,644,645]. Early-onset disease incidence declined an additional 29% after issuance of the revised guidelines in 2002, to 0.34 cases per 1000 live births from 2003-2007 [172].

Currently, all pregnant women should be screened in each pregnancy for group B streptococcal carriage at 35 to 37 weeks of gestation. The risk-based approach is an acceptable alternative only in circumstances in which the culture has not been performed or results are unavailable before delivery. Culture specimens should be obtained from the lower vagina and the rectum using the same or two different swabs. These swabs should be placed in a non-nutritive transport medium, transferred to and incubated overnight in a selective broth medium, and subcultured onto 5% sheep blood agar medium or colistin–nalidixic acid medium for isolation of GBS. At the time of labor or rupture of membranes, IAP should be given to all pregnant women identified antenatally as carriers of GBS. The indications for IAP are shown in Figure 12–11. Group B streptococcal bacteriuria during the current pregnancy or prior delivery of an infant with invasive group B streptococcal disease always is an indication for IAP, so antenatal screening is unnecessary for these women. If culture results are unknown at the onset of labor or rupture of membranes, the risk factors listed in Figure 12–11 should be used to determine the need to institute IAP. Women who present with preterm labor before antenatal group B streptococcal screening should have cultures obtained and IAP initiated. If labor ceases and cultures are negative, IAP is discontinued, and antenatal screening is performed at 35 to 37 weeks of gestation. If labor ceases and cultures are positive, some experts recommend oral amoxicillin for another 5 to 7 days.

Planned cesarean section before rupture of membranes and onset of labor constitute exceptions to the need for IAP for women colonized with GBS. These women are at extremely low risk for having an infant with early-onset disease. Culture-negative women who are delivered at 37 weeks of gestation or later need not receive IAP routinely, even when a risk factor is present. Therapeutic use of broad spectrum antibiotics in labor should be employed as is appropriate for maternal indications, such as intra-amniotic infection.

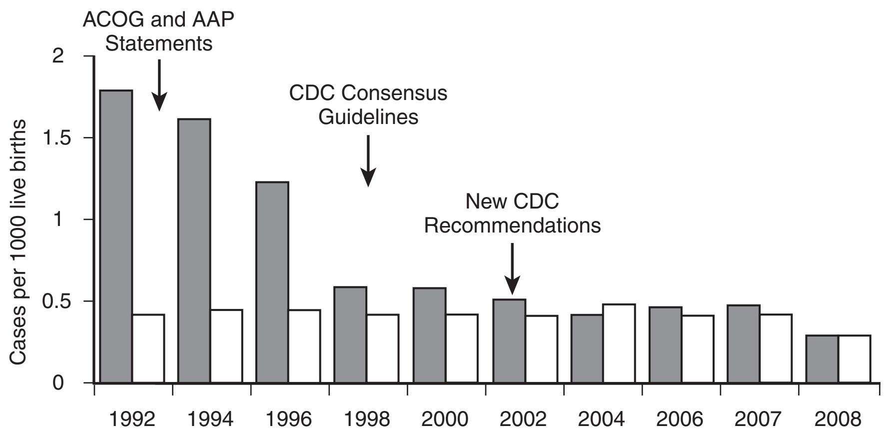

**FIGURE 12–10 Incidence of early-onset (*gray bars*) and late-onset (*white bars*) group B streptococcal disease from 1992-2008.** The dates of the initial prevention statements from the American College of Obstetricians and Gynecologists (ACOG) and the American Academy of Pediatrics (AAP) [624,625], the 1996 consensus guidelines from the Centers for Disease Control and Prevention (CDC) [639], and the revised 2002 CDC guidelines [612] are shown.

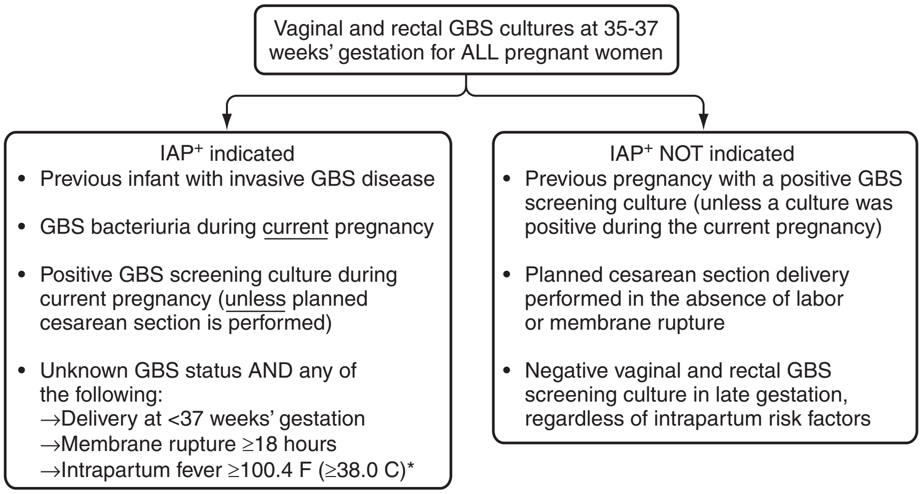


IAP+ = Intrapartum antibiotic prophylaxis.
*If chorioamnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS IAP.

**FIGURE 12–11** Revised recommendations for culture-based screening for maternal colonization with group B streptococci (GBS) and administration of intrapartum antibiotic prophylaxis (IAP). *(Adapted from Centers for Disease Control and Prevention. Prevention of perinatal group B streptococcal disease: revised guidelines from CDC. MMWR Morb Mortal Wkly Rep 51[RR-11]:1-22, 2002.)*

The recommended maternal intrapartum chemoprophylaxis regimen consists of penicillin G (5 million U initially and 3 million U every 4 hours thereafter until delivery) [612]. Penicillin or ampicillin given 4 or more hours before delivery reliably prevents vertical transmission and early-onset disease. Ampicillin administered as a 2-g intravenous loading dose and then 1 g every 4 hours until delivery is an alternative to penicillin [612]. The rationale for the high initial dose of the β-lactam antibiotic relates to the desired drug concentrations needed in the amniotic and vaginal fluids (peak approximately 3 hours after completion of the initial dose) to reduce substantially the number of GBS at either site. IAP "failures" typically occur when penicillin or ampicillin has been initiated 2 or less hours before delivery; clindamycin has been given without susceptibility testing, and clindamycin-resistant early-onset group B streptococcal neonatal sepsis ensued; or appropriate IAP is given in the setting of clinically apparent or silent intra-amniotic infection.

Prophylaxis for penicillin-allergic women must take into account increasing resistance among GBS to erythromycin and clindamycin. Women *not* at high risk for anaphylaxis (e.g., a rash without anaphylaxis or respiratory compromise) should receive cefazolin, 2 g intravenously as an initial dose and then 1 g every 8 hours until delivery. Cefazolin has pharmacokinetics similar to penicillin with respect to peak concentrations in serum and amniotic fluid of pregnant women. Women whose group B streptococcal isolates are tested and found to be clindamycin susceptible by D test and who are at high risk for anaphylaxis with penicillin can receive clindamycin at a dose of 900 mg every 8 hours. If susceptibility testing is unavailable or the results are unknown, or when isolates are resistant to clindamycin, vancomycin, 1 g intravenously every 12 hours until delivery, is an alternative for women with serious penicillin hypersensitivity reactions. Neither the pharmacokinetics of vancomycin in amniotic or vaginal fluids nor its efficacy in preventing early-onset disease has been investigated.

The risk of anaphylaxis from administration of penicillin is low. Estimates range from 4 events per 10,000 to 4 per 100,000 patients. Anaphylaxis associated with administration of a β-lactam antibiotic as IAP for the prevention of early-onset group B streptococcal infection has been reported, but is rare [171,646–648]. Most pregnant women reporting a penicillin allergy that is not anaphylaxis have negative skin test on hypersensitivity testing and are able to receive IAP with penicillin safely [649]. A fetal demise in association with new-onset penicillin allergy during IAP has been reported in a woman with rheumatoid arthritis [650]. No adult fatalities in association with IAP are reported, and the risk of a fatal event is low because the antimicrobials are administered in a hospital setting where medical intervention is readily available.

Numerous residual problems, barriers to implementation, and missed opportunities must be overcome to achieve maximal benefit from IAP [651–653]. Procedural issues, such as suboptimal culture processing and collection of cultures earlier than 5 weeks before delivery, constitute one set of problems. Laboratories may not adhere to recommended methods for isolation of GBS, a problem that remains despite the 2002 consensus recommendations and one that results in colonized women delivering infants with early-onset disease. Even optimal antenatal culture methods miss some women who are colonized at delivery, exposing their neonate to GBS and resulting in colonization or illness. Another problem is that women who are not screened adequately more often are medically underserved; women in their teens, blacks, and Hispanics are more likely than whites to receive inadequate prenatal care and prenatal testing, and are less likely to receive recommended prevention interventions.

Problems surround lack of recommended IAP in certain circumstances. The most prominent is lack of adherence to the 2002 recommendation for routine IAP in women who deliver before antenatal screening occurs (i.e., 35 to 37 weeks of gestation). These women should have vaginal and rectal cultures performed and routinely receive IAP, but this recommendation is the one least commonly implemented. Whether this is because delivery ensues too quickly to administer IAP, or the recommendation is

unclear to obstetric providers, or both, is unknown. Also, adherence to guidelines in penicillin-allergic women is suboptimal, and cefazolin as the appropriate IAP for women with a nonserious penicillin allergy is administered uncommonly [654]. Reliance on clindamycin as the alternative agent in women without serious penicillin allergy results in inadequate IAP in at least 20% of patients when antimicrobial susceptibility testing of colonizing isolates is not performed antenatally.

A final issue is a need for increased awareness of perinatal group B streptococcal infection. In one report, only 47% of women younger than 50 years of age reported having heard of group B *Streptococcus* [655]. Women with a high school education or less; with low household income; or reporting black, Asian/Pacific Islander, or "other" race had lower awareness than that noted in other women. Efforts to raise awareness should target women from groups that traditionally are medically underserved. Hospital infection control teams can contribute to these efforts by spearheading educational efforts toward effective implementation among hospital obstetric staff and laboratory personnel [642].

## Impact of Intrapartum Antibiotic Prophylaxis on Neonatal Sepsis

The efficacy of IAP in preventing early-onset group B streptococcal infection has been shown in numerous observational studies and in countries other than the United States when guidelines have been implemented [171,424,656–658]. The impact of increased use of IAP on the occurrence of sepsis caused by organisms other than GBS is a subject of ongoing evaluation. Concern exists that neonatal sepsis caused by organisms other than group B *Streptococcus* is increasing while group B streptococcal sepsis is decreasing and that the organisms causing non–group B streptococcal sepsis are likely to be ampicillin-resistant [659]. Surveillance trends are insufficient to establish a relationship between IAP for group B *Streptococcus* and *E. coli* sepsis risk, but single hospital–reported increases in *E. coli* sepsis that have occurred in preterm and very low birth weight infants are of concern [660]. A significant increase in the rate of early-onset sepsis caused by *E. coli* has been observed in multicenter studies, but only infants of very low birth weight (<1500 g birth weight) were evaluated [661]. In a multisite surveillance of trends in incidence and antimicrobial resistance of early-onset sepsis, stable rates of sepsis caused by other organisms were found, but an increase in ampicillin-resistant *E. coli* was observed among preterm but not term infants [662].

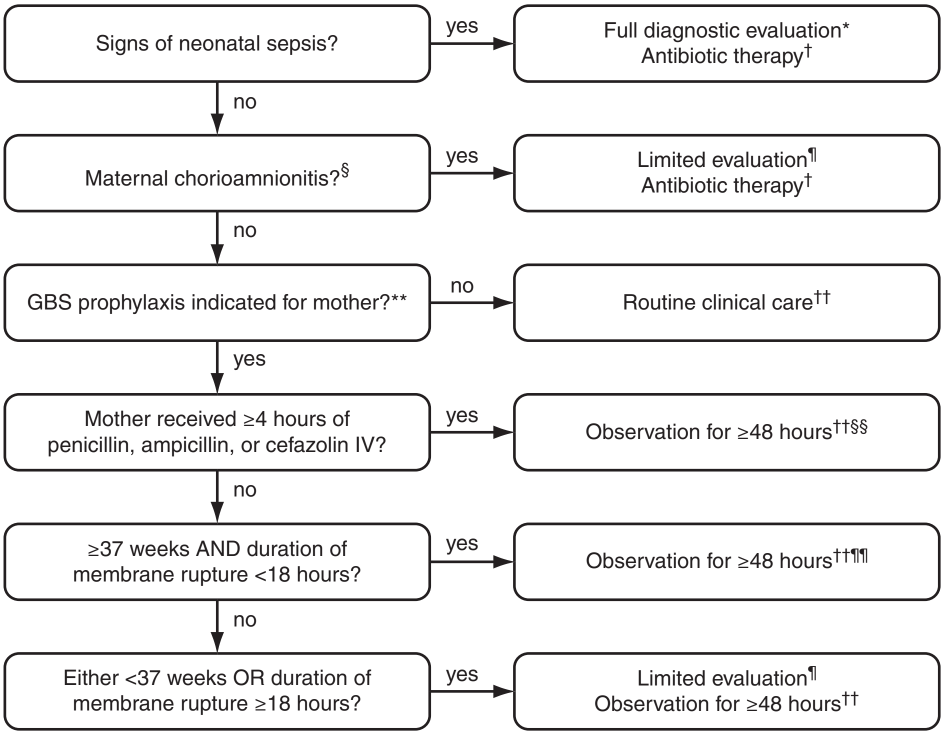
A relationship between neonatal death caused by ampicillin-resistant *E. coli* and prolonged antepartum exposure to ampicillin was noted by Terrone and colleagues [663]. In another report, the frequency with which ampicillin-resistant Enterobacteriaceae were isolated was similar after exposure to ampicillin or penicillin [664]. Repeat cultures 6 weeks postpartum revealed no increase in antibiotic resistance in either GBS or *E. coli* from women who had received IAP [665]. Ongoing population-based surveillance is required to monitor these trends and to identify possible reasons for the increase in ampicillin-resistant *E. coli* infections in preterm neonates, in particular, the use of antenatal antimicrobial agents other than IAP [666,667].

## Management of Neonates Born to Mothers Receiving Intrapartum Antibiotic Prophylaxis

Management of infants is based on the neonate's clinical status, whether the mother had chorioamnionitis, an indication for IAP, or adequate duration of IAP, and gestation (Fig. 12–12) [612]. If an infant has any signs of sepsis, a full diagnostic evaluation, including complete blood cell count and differential, blood culture, and chest radiograph if the neonate has respiratory signs, and empirical therapy should be initiated pending laboratory results. A lumbar puncture, if feasible, should be performed. Although published reports vary, a minimum of 10% and a maximum of nearly 40% of infants with meningitis have a negative blood culture [532]. If lumbar puncture is deferred and therapy is continued for more than 48 hours because of suspected infection, CSF should be obtained for routine studies and culture. Depending on the CSF results, therapy appropriate for sepsis or presumed meningitis is given.

If a woman receives broad-spectrum antibiotics for suspected chorioamnionitis, her healthy-appearing infant should have a full diagnostic evaluation excluding a lumbar puncture, and most experts would initiate empirical therapy pending culture results regardless of the clinical condition at birth, gestational age, or duration of antibiotics before birth. This approach is based on the infant's exposure to suspected or established infection. The duration of therapy is based on results of cultures and the infant's clinical course (see "Treatment" section). If the infant is healthy-appearing, but has a gestational age of less than 35 weeks, some experts would perform a limited evaluation that includes complete blood count and blood culture, without regard to the duration of maternal IAP. Empirical therapy need not be initiated, unless signs of sepsis develop or the infant is very immature. Healthy-appearing infants with a gestational age of at least 35 weeks whose mothers received intravenous penicillin, ampicillin, or cefazolin less than 4 hours before delivery should be observed closely without a diagnostic evaluation. If the infant is healthy-appearing and has a gestational age of 35 weeks or more, and the mother received penicillin, ampicillin, or cefazolin 4 hours or more before delivery, routine care is advised.

The recommended interval of observation for neonates undergoing a limited evaluation is 48 hours. The approach presented in Figure 12–12 is not to be taken as an exclusive management pathway. Hospital discharge at 24 hours of age can be reasonable under certain circumstances, specifically when the infant is born after the mother has received a β-lactam as IAP for 4 hours or longer before delivery, has a gestational age of 38 weeks or more, and is healthy-appearing. Other discharge criteria should be met, and the infant should be under the care of a person able to comply with instructions for home observation [612,668]. The risk of bacterial infection in healthy-appearing newborns is low. Outcomes



* Full diagnostic evaluation includes CBC with differential, platelets, blood culture, chest radiograph (if respiratory abnormalities are present), and LP (if patient stable enough to tolerate procedure and sepsis is suspected).

† Antibiotic therapy should be directed towards the most common causes of neonatal sepsis including GBS and other organisms (including gram negative pathogens), and should take into account local antibiotic resistance patterns.

§ Consultation with obstetric providers is important to determine the level of clinical suspicion for chorioamnionitis. Chorioamnionitis is diagnosed clinically and some of the signs are non-specific.

¶ Limited evaluation includes blood culture (at birth), and CBC with differential and platelets. Some experts recommend a CBC with differential and platelets at 6-12 hours of age.

** GBS prophylaxis indicated if one or more of the following: (1) mother GBS positive at 35-37 weeks' gestation, (2) GBS status unknown with one or more intrapartum risk factors including <37 weeks' gestation, ROM≥18 hours or T≥100.4°F (38.0°C), (3) GBS bacteriuria during current pregnancy, (4) history of a previous infant with GBS disease.

†† If signs of sepsis develop, a full diagnostic evaluation should be done and antibiotic therapy initiated.

§§ If ≥37 weeks' gestation, observation may occur at home after 24 hours if there is a knowledgeable observer and ready access to medical care.

¶¶ Some experts recommend a CBC with differential and platelets at 6-12 hours of age.

**FIGURE 12–12** Algorithm for prevention of early-onset GBS disease among newborns.

among infants whose mothers receive IAP are better than among infants whose mothers do not receive IAP. Rehospitalization is uncommon among these latter infants, however [669].

The influence of maternal IAP on the clinical spectrum of early-onset infection in term infants has been evaluated [669–671]. Exposure to antibiotics in labor does not change the clinical spectrum of disease or the onset of clinical signs of infection within 24 to 48 hours of birth for infants with early-onset group B streptococcal infection. Infants whose mothers have received IAP are less likely to be ill, to require assisted ventilation, or to have proven bacterial infection [669]. These infants are not more likely to undergo invasive procedures or to receive antibiotics [670]. The number of infants undergoing evaluation for sepsis has decreased in association with implementation of IAP guidelines, and among group B *Streptococcus*–negative women, ordering of laboratory tests has diminished by almost 40% [672].

## Chemoprophylaxis for the Neonate

Chemoprophylaxis for neonates at birth continues to be advocated by some investigators. Three decades ago, Steigman and colleagues [673] found no cases of early-onset group B streptococcal infection among 130,000 newborns who received a single intramuscular injection of penicillin G (50,000 U) at birth as prophylaxis for gonococcal infection. Neonates with possible in utero acquisition of infection who were ill at birth did not receive prophylaxis and were excluded from the analysis. Pyati and coworkers [674] evaluated more than 1000 neonates with birth weights of less than 2000 g in whom a blood culture was obtained before penicillin was administered. In these high-risk infants, penicillin prophylaxis at birth was ineffective in preventing group B streptococcal bacteremia or in altering the mortality rate associated with infection.

A few centers use a combined maternal and neonatal protocol that advocates a risk-based maternal IAP approach coupled with administration of a single dose of

intramuscular penicillin to all infants within 1 hour of birth [675–677]. Observational studies showed a 76% reduction in early-onset infection to 0.47 per 1000 live births when rates for the 5 years from 1986-1994 were compared with rates from 1994-1999.

In the special circumstance of an apparently nonaffected sibling in a twin or multiple birth with early-onset [332,333] or late-onset [333] group B streptococcal disease, the well-appearing sibling of a neonate with invasive infection is at increased risk of developing group B streptococcal disease. At the time of diagnosis of group B streptococcal disease in the index patient of a multiple birth, the other infant or infants should be assessed clinically [333]. If signs of infection are noted, cultures of blood and CSF should be obtained, and empirical antimicrobial treatment should be initiated until laboratory results become available. If cultures yield group B *Streptococcus*, a full course of treatment is appropriate. If findings from the clinical assessment are unremarkable, management should be undertaken on a case-by-case basis. The risk for a poor outcome when the second twin is not evaluated until clinical signs of infection are apparent warrants caution in this circumstance. Even when empirical therapy is given and invasive infection is excluded, later onset is possible [678].

## IMMUNOPROPHYLAXIS

The most promising approach to prevention of group B streptococcal disease is immunoprophylaxis [613,679]. The underlying principle is that IgG directed against CPS of GBS, critical for protection against invasive disease, are provided by passive or active immunization. Human sera containing a sufficient concentration of CPS-specific antibody have been shown in animal models of infection to protect against lethal challenge with each of the major group B streptococcal types [350,680]. Provision of protective levels of type-specific immunity to the newborn theoretically can be achieved by passive or active maternal immunization. Passive immunotherapy for the mother would require development of hyperimmune preparations of human immunoglobulin for intravenous use, would be expensive, and would require many hours of infusion before delivery to provide fetal serum levels, but animal studies indicate the potential usefulness of such an approach [681,682].

The first candidate group B streptococcal vaccine, a purified type III CPS, underwent testing in healthy adults in 1978 [359]. Subsequently, types Ia and II CPS vaccines were studied [683]. Although these vaccines were well tolerated and elicited primarily IgG class response within 2 to 4 weeks, the immunogenicity was variable. It was discovered that nearly 90% of adults had very low preimmunization serum concentrations of CPS-specific antibodies in association with presumed immunologic naïvete. These low levels predicted a poor immune response in many, so that only 40% and 60% developed significant type-specific antibody responses after immunization with type Ia and type III CPS vaccines. By contrast, 88% of adults immunized with type II CPS vaccine responded with fourfold or greater increases in type II CPS–specific antibodies.

These early trials verified the feasibility of immunization as an approach to prevent group B streptococcal disease and revealed the need to develop candidate vaccines with enhanced immunogenicity. The first study conducted in pregnant women was an encouragement to the ultimate potential success of a group B streptococcal vaccine program [410]. Among 25 pregnant responders to a type III CPS group B streptococcal vaccine, 90% delivered infants with substantial levels of specific antibody to the type III CPS in cord sera that promoted functional activity in vitro throughout the first 3 months of life in most instances.

Development of the first group B streptococcal CPS conjugate vaccine, type III CPS–tetanus toxoid, was driven by the prominence of type III among infants with early-onset and late-onset disease and by its dominance as a cause of meningitis. Type III CPS was linked covalently to monomeric tetanus toxoid by reductive amination coupling chemistry [684]. Group B streptococcal CPS–protein conjugate vaccines of all clinically important types subsequently were developed and found to be immunogenic and protective in experimental animals [684–687,689]. The first clinical evaluation of the type III CPS–tetanus toxoid conjugate showed greater than fourfold increases in postimmunization CPS-specific IgG in 90% of healthy nonpregnant women [690]. The vaccine was well tolerated, and the antibodies, predominantly of the IgG class, were functional in vitro and protective in a murine model of infection.

Conjugate vaccines to each of the clinically relevant group B streptococcal CPS types causing invasive disease have been tested in nearly 500 healthy adults 18 to 50 years old [688,690–692]. Systemic responses, such as low-grade fever, chills, headache, or myalgias, always short-lived, were observed in less than 2% of volunteers. Local reactions were frequent but mild, typically consisting of pain without erythema or swelling, and resolved within 48 to 72 hours. Immune responses to each of the conjugate vaccines, with the exception of type V, are dose-dependent. Doses of 4 to 15 μg of the CPS component have elicited greater than fourfold increases in CPS-specific IgG in 80% to 93% of recipients of type Ia, Ib, II, III, and V conjugates at 8 weeks after immunization. Evaluation of a vaccine combining type II and type III CPS, each conjugated to tetanus toxoid, showed no immune interference compared with response after administration of one of the monovalent vaccines [693].

A phase 1 randomized placebo-controlled, double-blinded trial of type III CPS–tetanus toxoid conjugate vaccine was conducted in 30 healthy pregnant women at 30 to 32 weeks of gestation [704]. Immunization was well tolerated. Geometric mean concentrations of IgG to type III CPS from immunized women were significantly increased from preimmunization values and correlated well with infant cord values. Sera from the infants of vaccinated women collected at 1 and 2 months of age promoted in vitro opsonization and killing of type III GBS by human neutrophils.

One alternative strategy for the preparation of group B streptococcal conjugate vaccines is to construct “designer” glycoconjugate vaccines with size-specific antigens and site-controlled coupling that optimizes the magnitude and specificity of the antipolysaccharide response [694]. An oligosaccharide-based tetanus toxoid conjugate vaccine against type III GBS was synthesized to retain the antigenic specificity of the native polysaccharide and has been shown to be immunogenic in mice [695]. Conjugate

vaccine size, CPS molecular weight, and the degree of polysaccharide-protein cross-linking all are important considerations in optimizing immunogenicity of candidate vaccines [67].

Use of proteins that are conserved across most group B streptococcal serotypes offers another strategy for vaccine development. The C protein could be an alternative to tetanus toxoid as the protein component of a conjugate vaccine [680,687,696]. Invasive disease, but not colonization, elicits α C–specific and β C–specific IgM and IgG in adults [697,698]. A type III polysaccharide–C protein conjugate vaccine theoretically could prevent most systemic infections [699]. A recombinant β C protein modified to eliminate its IgA-binding site conjugated to type III CSP has been shown to be immunogenic in mice, inducing polysaccharide and protein-specific functional IgG [700]. The group B streptococcal surface proteins, Rib, Sip, and C5a peptidase, each have been shown to elicit antibodies that are protective in experimental models of group B streptococcal infection [701–703]. Their roles in human infection are not established.

The discovery that surface-associated pilus-like islands are distributed widely among group B streptococcal clinical isolates potentially paves the way for the development of pilus island–based vaccines. An entire pilus island has been transferred from group B *Streptococcus* to a nonpathogenic species. Mucosally delivered *Lactococcus*-expressing pilus island 1 protected mice from challenge with pilus 1–containing group B streptococcal strains [10]. Pilus islands 1, 2a, and 2b, alone or in combination, were identified on each of 289 group B streptococcal isolates from infants and adults with invasive disease, and most were highly surface expressed [11]. A combination of the three pilus-island components conferred protection against all tested group B *Streptococcus* challenge strains. A vaccine exclusively constituted by pilus components in concept could be broadly efficacious in preventing infections caused by GBS [11].

Because most pregnant women have low concentrations of type-specific IgG in their sera, a practical approach to immunoprophylaxis would be immunization of women during adolescence, before pregnancy, or late in pregnancy (i.e., early third trimester) [593]. In view of the substantial disease burden in nonpregnant adults, targeted adult immunization (e.g., diabetics or adults ≥65 years old) also is an attractive prevention strategy. Types Ia, III, and V GBS account for 75% to 85% of infections and, together with types Ib and II, for most invasive disease in infants and adults [143,146,699,704]. The production of a trivalent or a pentavalent conjugate vaccine is technically achievable. Physicians and their patients and pharmaceutical industry leaders must perceive this mode of prevention to be of high benefit and negligible risk, especially if pregnant women are to be included in the target population. The cost of developing suitable vaccines, although substantial, is considerably less than the death, disability, and treatment associated with these infections [623,705]. If the prevention of group B streptococcal disease is to become a reality, however, physicians, public health officials, parents, and patients must join together as advocates for pregnant women, neonates and young infants, and at-risk adults.

# CHAPTER 13

# LISTERIOSIS

Robert Bortolussi ✪ Timothy L. Mailman

## CHAPTER OUTLINE

*Listeria monocytogenes*, a gram-positive facultative bacillus, is a frequent veterinary pathogen that causes abortion and meningoencephalitis in sheep and cattle. Infection in a wide variety of other mammals is also recognized. Human disease is uncommon, but is potentially severe and occurs most frequently in neonates, in women during pregnancy, and in elderly or immunosuppressed patients. Nyfeldt [1] described *Listerella hominis* as the cause of human infectious mononucleosis in 1929, but subsequent experience indicates that human infections parallel animal illness, with sepsis and meningoencephalitis as the primary forms of invasive disease.

Murray and coworkers [2] provided the first notable description of the organism in 1926. An epizootic outbreak among laboratory rabbits and guinea pigs provided an isolate, subsequently named *Bacterium monocytogenes*. The greatest incidence and mortality occurred in recently weaned newborn animals. Later, Pirie [3] isolated the organism from South African gerbils and termed it *Listerella hepatolytica*, in honor of Lord Lister. Pirie [4] subsequently revised the name to *Listeria monocytogenes*, the currently accepted species name.

# ORGANISM

## MORPHOLOGY

The morphology of *L. monocytogenes* varies with the age of the culture. In clinical specimens, Gram stains typically show short intracellular and extracellular gram-positive rods. Careful interpretation of morphology is crucial. Over-decolorized *Listeria* organisms in cerebrospinal fluid have led to a misdiagnosis of *Haemophilus influenzae* meningitis [5]. Confusion with pneumococcal meningitis is also possible; on primary culture, early bacterial growth may yield coccobacillus morphology in which short chains are occasionally seen. Older cultures may be variable.

## MOTILITY

All strains of *L. monocytogenes* are motile, distinguishing the organism from *Erysipelothrix* and most species of *Corynebacterium*. A characteristic "tumbling" motility occurs in hanging drop preparations of primary cultures grown at room temperature [6]. In addition, tubes of semisolid motility medium produce a distinctive "umbrella" pattern at room temperature when inoculated with the stab technique. Electron microscopic studies and protein electrophoresis have shown that *L. monocytogenes* fails to express flagellar protein and loses motility at 37° C [7].

## CULTURE AND IDENTIFICATION

*L. monocytogenes* grows well on common media, including brain-heart infusion, trypticase soy, and thioglycolate broths. Primary isolation from normally sterile sites can be accomplished on blood agar. Growth in ambient air occurs at temperatures of 4° C to 37° C, with fastest growth rates occurring at 30° C to 37° C. Selective media, such as Oxford, modified Oxford, or PALCAM agar (polymyxin B, acriflavine, lithium chloride, ceftazidime, aesculin, and mannitol), should be used for isolation from contaminated specimens and have largely replaced cold enrichment techniques [8,9].

After 48 hours at 37° C on 5% sheep blood agar, colonies are 0.2 to 1.5 mm in diameter. Narrow zones of β-hemolysis may be visualized—often only after moving

DOI: 10.1016/B978-1-4160-6400-8.00013-4

the colony. Catalase test is positive (rare reports of catalase-negative isolates exist) [10]. *Listeria seeligeri* and *Listeria ivanovii* are also β-hemolytic, but generally are nonpathogenic in humans. Speciation is aided by the Christie-Atkins-Munch-Peterson (CAMP) reaction using *Staphylococcus aureus* for *L. monocytogenes* and *L. seeligeri* and *Rhodococcus equi* for *L. ivanovii* [11].

Discrimination among *Listeria* species is aided by sugar fermentation patterns. *L. monocytogenes* produces acid from L-rhamnose and α-methyl-D-mannoside, but not from xylose. *L. ivanovii* and *L. seeligeri* produce acid from D-xylose only. Automated systems (e.g., Vitek, Microscan Walkway, Siemens, Berlin), commercial biochemical strips (e.g., API Listeria Biomerieux, MICRO-ID Listeria), DNA probes (e.g., AccuProbe Listeria Culture Identification Test, Remel, Kansas City, MO) and home-brew and commercial polymerase chain reaction (PCR, Gen-Probe Life Sciences, Manchester, UK) assays (e.g., LightCycler *Listeria monocytogenes* Detection Kit, Roche, Basel, Switzerland) are now available to aid in the identification of *L. monocytogenes* in clinical microbiology laboratories.

## ANTIGENIC STRUCTURE AND TYPING SYSTEMS

There are 13 known serotypes of *Listeria*, distinguished on the basis of somatic (O) and flagellar (H) antigens [12,13]. Serotypes 1/2a, 1/2b, and 4b cause most animal and human disease. Serotyping has little impact on clinical management, but has a role in public health during epidemiologic investigations. Before the 1990s, phage typing was used for epidemiologic investigations—particularly in tracing sources of food-borne *Listeria* outbreaks when serotyping failed to discriminate between epidemic and nonepidemic strains [14–16]. Such strains often remained nontypable.

Molecular typing has provided new levels of discriminatory power. Multilocus enzyme electrophoresis, although not directly DNA based, has proven reliable in distinguishing strains based on electrophoretic mobility of enzymes [17]. Multilocus enzyme electrophoresis is limited, however, by the failure of many nucleotide and amino acid changes to alter net enzyme charge and electrophoretic mobility [18,19].

Analysis of *Listeria* DNA has enhanced the discriminatory power of strain typing [20,21]. Molecular subtyping approaches have been DNA fragment or sequence based. One fragment-based analysis creates microrestriction patterns using high frequency–cutting enzymes (restriction endonucleases). The technique has been used in epidemiologic investigations, but its complex results make strain comparison difficult. Ribotyping simplifies this process by examining only DNA fragments from the ribosomal genes [18]. The automation of ribotyping into commercially available systems has enabled rapid identification of disease clusters and immediate typing of *Listeria* strains.

DNA macrorestriction pattern analysis using pulsed-field gel electrophoresis (PFGE) was adopted by the World Health Organization for typing in 2003 [22]. PFGE is highly discriminating and reproducible—even for serotype 4b strains that are poorly typed by most other methods. The U.S. Centers for Disease Control and Prevention (CDC) created PulseNet, a network of laboratories using standardized PFGE protocols to subtype food-borne bacterial pathogens. Using the Internet for reporting and comparing PFGE patterns, laboratories can now identify regional or national clusters that could be missed with localized reporting.

DNA amplification–based typing methods, such as random amplification of polymorphic DNA, have been shown to have a high degree of discriminatory power as well. The primary drawback at present is the lack of standardization. The combination of DNA amplification with automated sequencing provides ultimate discriminatory power—to the nucleotide level—and is becoming more widely available.

## VIRULENCE FACTORS

Food-borne outbreaks of *L. monocytogenes* infections led to intense interest in the characterization of its virulence factors. Similar to *Salmonella typhimurium*, *Yersinia enterocolitica*, and *Legionella pneumophila*, *Listeria* has become a model organism for intracellular parasitism [13,23–25]. In tracing the journey of an organism from ingestion to successful replication in the host, we can appreciate the incredible adaptations that have occurred.

*Listeria* have the ability to survive environmental change [26]. In response to stressors such as thermal variation, acidic pH, and osmotic challenge, stress response genes—encoding a set of conserved proteins—are upregulated and have roles such as repair and removal of damaged bacterial proteins [27]. Stress response genes are largely regulated by sigma factor B (*sigB* gene), also responsible for stress resistance in other bacterial species [28]. Environmental survival is intricately linked to virulence. In animal models, acid-adapted *Listeria* survive low gastric pH, leading to higher bacterial loads in the intestine and mesenteric lymph nodes after oral infection [29].

Having survived gastric acidity, *Listeria* induce their uptake into host intestinal cells via phagocytic vacuoles. The internalin (Inl) family of bacterial surface proteins mediate attachment to mammalian cells [13,30–32]. InlA and InlB promote engulfment and internalization of bacteria by normally nonphagocytic cells. E-cadherin, the glycoprotein receptor for InlA, is present on the surface of gastrointestinal epithelial cells known to be targets for *Listeria* entry. Lecuit and colleagues [33] identified a single proline residue in E-cadherin that mediates species specificity—the first potential molecular explanation of bacterial–host species specificity. InlB, a 67-kDa protein, has two receptors, Met and gC1q-R (a cellular ligand for the C1q complement fraction), which confer a tropism for hepatocytes and brain microvascular epithelial cells. In1J, another attachment protein, is expressed only by organisms growing in vivo [32]. A fourth protein, invasion-associated protein (iap or p60), is secreted by invasive *Listeria* strains and is a major antigen for the protective immune response against *L. monocytogenes* [34,35].

Inside the cell, *Listeria* engineers its own escape from the oxidative stress of the phagolysosome [13,36]. Invasive strains of *L. monocytogenes* produce listeriolysin O (LLO) (a sulfhydryl-activated hemolysin similar to streptolysin O). LLO (*hly* gene), which is activated specifically at low pH and disrupts the integrity of phagosome membranes, allows *Listeria* to escape into the cytosol where it begins intracellular replication [37,38]. Here the bacterial surface

protein ActA—product of the *actA* gene—triggers polymerization of host cell actin into a "comet tail" that enables intracellular movement and cell-to-cell spread of the pathogen [38–40]. *Listeria* move along these actin filaments to the cell membrane, eventually pushing it outward in a pseudopod-like extension (also termed a *listeriopod*), which is engulfed by neighboring cells as a double-walled secondary phagosome.

Escape from the primary phagosome and the secondary phagosome is also mediated by phospholipase C (*plcA* gene) and a lecithinase (*plcB* gene), which contribute to lysis of phagosomal membranes. Mutations of the *plcA* and *plcB* genes significantly reduce virulence [13,31,41]. A metalloprotease encoded by the gene *mpl* converts lecithinase into its active form [42]. Cell-to-cell spread continues in this cycle with *Listeria* protected the entire time from extracellular host defenses (e.g., antibody, complement, professional phagocytes).

Virulence gene expression is controlled by regulatory genes. The gene, *prfA* (positive regulatory factor A), controls expression of *hly* and *plcB* via PrfA, its protein product [43]. PrfA is the main switch of a regulon containing most virulence genes in *Listeria*. This transcription factor promotes expression of certain genes (*hly*, *plcB*) and down-regulates others (the motility-associated genes *motA* and *flaA*) [44], implying a global regulatory role [45]. PrfA/*prfA*–induced regulation is influenced by the bacteria's physicochemical environment. Thermoregulation is one example: PrfA-dependent transcription is minimal at less than 30° C (environmental temperature), but is induced at 37° C (body temperature of mammals) [46,47].

The monocytosis initially observed in animals infected with *L. monocytogenes* has been partially explained. A phospholipid, monocytosis-producing agent, has been isolated that produces monocytosis in rabbits [48]. Monocyte production is stimulated by an endogenous mediator induced by monocytosis-producing agent [49].

## EPIDEMIOLOGY AND TRANSMISSION

### NATURAL RESERVOIR AND HUMAN TRANSMISSION

*Listeria* species are ubiquitous in nature, with a natural habitat in decaying plant matter [50]. Spoiled silage seems to be a source of infection for ruminant animals [51]. Fecal carriage of *L. monocytogenes* in animals plays a role in the organism's persistence by providing an enrichment cycle.

Although direct transmission of *L. monocytogenes* to humans from infected animals has been described, [52,53] most human infection is acquired through ingestion of contaminated food [54,55]. The first outbreak confirming an indirect transmission from animals was reported from Canada [16]. In this outbreak, cabbage, stored in the cold over the winter, were contaminated with *Listeria* through infected sheep manure. Clinical disease developed in pregnant women and immunocompromised patients who subsequently consumed the cabbage. Large outbreaks caused by contaminated foods continue to occur in North America and Europe [56–60]. The relative resistance of *Listeria* to high temperatures and its ability to multiply at low temperatures provide opportunities for heavy contamination of dairy products if pasteurization has been carried out improperly [61,62]. Outbreaks have been commonly associated with prepared meat products, including turkey and deli meats, paté, hot dogs, and seafood products [60,63–68]. *Listeria* has been identified as the leading cause of death from food-borne infection in the United States and France [69,70]. Risk of an outbreak caused by contaminated food seems to be related to a high inoculum of *L. monocytogenes* in the food [71].

The improved ability to detect *L. monocytogenes* by selective culture and molecular methods has provided the opportunity to examine food eaten by patients who have developed sporadic cases of listeriosis [72]. It has been confirmed that most sporadic cases of listeriosis are caused by ingestion of contaminated foods [73–75]. These studies implicated a wide variety of foods, including melons, hummus, undercooked chicken, and soft cheeses, as significant sources of sporadic disease. A review of food-borne listeriosis has been published more recently [76].

### OCCURRENCE

*L. monocytogenes* causes an estimated 2500 serious illnesses and 500 deaths annually in the United States. Active surveillance programs in several countries have suggested an annual incidence of 0.2 to 0.7 cases per 100,000 population [56,57,75,77–80]. With the exception of France and Germany, incidence has been steady or declining [56,59,75]. Countries with active surveillance programs have reported the highest incidence of disease.

*L. monocytogenes* may cause symptomatic gastroenteritis, a nonreportable condition. Fecal carriage of *Listeria* is uncommon in settings not associated with outbreak [81], but may be 26% in household contacts of patients with listeriosis [55] and 8% in the community during outbreaks [82].

The distribution of serovars causing disease may not be uniform. In North America, serovars 4b and 1/2 account for 95% of strains, with serotype 4b being the most common overall [83]. In Spain and Germany, serovar 4b is predominant [84,85]. whereas in Denmark serovar 1/2 is common [58]. The significance of these geographic differences is unknown.

The incidence of listeriosis is highest among newborn infants. Perinatal and newborn infection represents 30% to 40% of the total caseload in humans [77,78]. The true incidence is probably much higher, however, because spontaneous abortion and stillbirth caused by *Listeria* is largely unrecognized unless bacterial cultures are obtained from tissue. The incidence of perinatal and neonatal listeriosis is 2 to 13 per 100,000 live births [57,84–86]. It is possible that a lower inoculum may cause infection in pregnant women compared with the general population. No differences in carriage rates between pregnant women and nonpregnant individuals have been found in fecal and vaginal specimens [87]. Fecal carriage may lead to vaginal colonization and be responsible for the development of late-onset infection in infants born of healthy mothers.

Most documented human cases of listeriosis occur in high-risk adult populations, including elderly adults and adults with compromised immune function (Table 13–1). Sepsis and meningitis are the most frequent resulting

**TABLE 13–1** Individuals at High Risk of Listeriosis

| |
|---|
| ***Pregnant Women*** |
| Risk of listeriosis is about 20 times higher in pregnant women than in nonpregnant healthy adults |
| About one third of listeriosis cases are diagnosed in pregnant women |
| Pregnant women with listeriosis are at increased risk of spontaneous abortion, preterm delivery, or stillbirth |
| ***Newborns*** |
| Newborns are at greater risk of developing severe infection than pregnant women |
| Newborns may present clinically with |
| Early-onset listeriosis (transmitted via placenta and usually diagnosed as sepsis in the first day of life) |
| Late-onset infection (≥7 days of life, high rate of meningitis [>90%]) |
| ***Elderly Adults and Immunocompromised Patients*** |
| About 50% of all cases of listeriosis occur in individuals ≥60 yr old |
| Immunocompromised patients include patients with cancer, diabetes, or kidney disease |
| Listeriosis is 300 times more likely to occur in patients with HIV/AIDS than in healthy adults |
| Other immunocompromised patients include |
| Patients receiving immunosuppressive drug therapy (e.g., high-dose glucocorticosteroid, tumor necrosis factor inhibitor) |
| Transplant patients receiving antirejection drug therapy |

illness [78]. Louria and coworkers [88] initially described this infection in patients with malignancies, but various other conditions have been reported in association with invasive listeriosis [89,90]. Susceptibility in laboratory animals is increased by the administration of corticosteroids [91], cyclosporine [92], and prostaglandins [93], and the human experience parallels these studies. Renal transplantation seems to be a particularly significant risk factor, and a nosocomial outbreak has been reported in this population [94]. Hemochromatosis with increased iron stores may also predispose to infection. Patients with human immunodeficiency virus (HIV) infection have a 400-fold to 1000-fold increased risk of acquiring invasive listeriosis compared with HIV-negative subjects [95]. Alcoholism, diabetes, and cirrhosis [96] also contribute to infection, although community-acquired listeriosis may occur spontaneously in patients with no underlying predisposing conditions [97]. Animal studies [98] and one outbreak of human listeriosis [99] suggest that decreased gastric acidity may also predispose to invasive infection in patients with immunosuppressive conditions.

## NOSOCOMIAL TRANSMISSION

Although most cases of listeriosis occur in the community, nosocomial listeriosis in neonates and adults has been described [100–107]. Person-to-person transmission caused by poor infection control techniques is likely to be responsible for most of these small clusters. Among clusters reported in newborns, the index case may manifest as early-onset infection, and subsequent cases may manifest as late-onset listeriosis. Multiple cases of early-onset disease in the same unit may suggest the possibility of food-borne disease in the community. Nosocomial infection among adults in one outbreak [99] seemed related to ingestion of contaminated food in the hospital or within 2 weeks of hospitalization. Clear-cut nosocomial infection has been shown in a neonatal outbreak in Costa Rica [108]. In this outbreak, the index case had early-onset disease and was bathed with mineral oil that became contaminated with the epidemic isolate. Subsequent bathing of other infants with the same oil led to late-onset disease in those infants.

# PATHOGENESIS

## HOST RESPONSE IN NORMAL ADULTS

The pathogenesis of listeriosis in humans is still poorly understood. Because food is the most common source of outbreak and sporadic cases, the gastrointestinal tract is thought to be the usual portal of entry into the host. Although *L. monocytogenes* is probably ingested frequently through contaminated food, the incidence of clinical disease in humans is relatively low [78]. This suggests the organism has relatively low virulence, a concept supported by the high concentration of organisms required to cause infection in the normal host [109].

The entry of *L. monocytogenes* into cells in the intestine is mediated by interaction of an *L. monocytogenes* surface protein, InlA, with its host cell receptor, E-cadherin. The InlA–E-cadherin interaction is species-specific and relies on an amino acid sequence found in only a few animal species, including humans [110]. Translocation of *Listeria* across the intestinal mucosa occurs very rapidly in humans and without histologic evidence of inflammation in the bowel wall [25]. The organism is transported to the liver within minutes of ingestion. This rapid process seems to be independent of the known *Listeria* virulence factors because mutant strains lacking such factors arrive at the liver roughly at the same time as their wild-type parent strains [24].

The first stage of the battle between bacteria and host occurs in the liver [111]. Within hours of ingestion, macrophages of the liver (Kupffer cells) and spleen capture and destroy most of the inoculum. Over the next 3 days, a nonspecific, T cell–independent phase of innate host resistance is operative. Since the 1960s, it was known that *L. monocytogenes* can survive within Kupffer cells that line the hepatic sinusoids. In the late 1980s, it was also appreciated that *Listeria* can infect nonphagocytic cells (e.g., epithelial, hepatocellular, and fibroblast cell lines), providing the organism with an intracellular environment temporarily sheltered from phagocytic cells and soluble effectors of host defense [36,112,113].

Although proteins on the surface of *Listeria*, such as InlA, InlB, and p60, may identify important factors associated with entrance into the cell in vitro [31,34,114], they do not fully explain intracellular spread and multiplication of the organism in vivo [115]. During the early course of infection, *L. monocytogenes* resides within a vacuole (for nonphagocytic cells) or a phagosome (in monocyte/macrophage-derived cells) (Fig. 13–1). Lysis of the

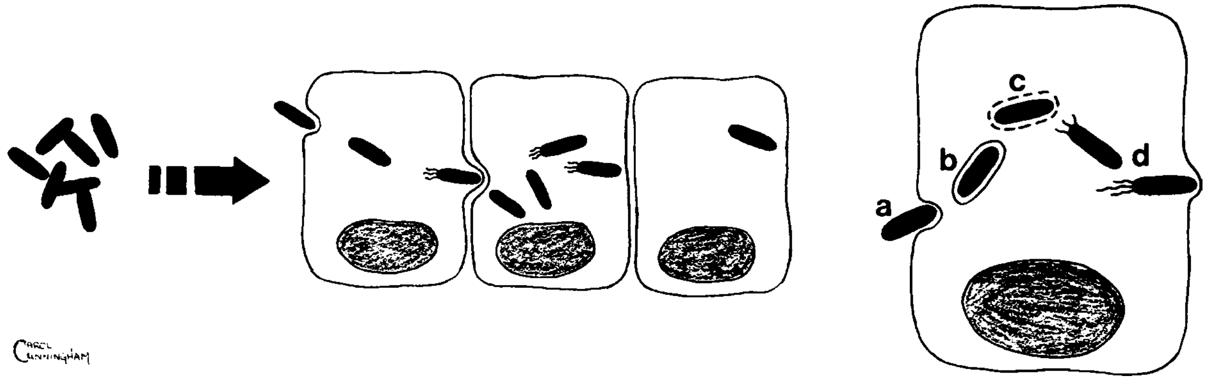

**FIGURE 13–1 Cellular invasion by *Listeria monocytogenes*.** Attachment of *L. monocytogenes* to the surface of cell membrane (*a*) is determined by a family of bacterial surface proteins including internalins (IntA and IntB). When internalized (*b*) within a vacuole (*c*), listeriolysin O (LLO) can lyse the vacuole membrane, liberating the bacteria into the cytoplasm. Bacterial surface ActA induces polymerization of cellular actin, which concentrates at one end of the bacterium. This "comet tail" (*d*) provides propulsion for the organism to move through the cytoplasm and into adjacent cells where the intracellular process begins again.

phagosome or vacuole is mediated by Listeriolysin O and non-Listeriolysin O proteins [38,116–118]. LLO may also increase the virulence of the organism by contributing to the elimination of immune T cells [119].

Bacterium-derived phospholipase C, a metalloprotease-mediated lysin, and other virulence factors also contribute to escape of *L. monocytogenes* from vacuoles and phagosomes [24,36,120,121]. Release of *L. monocytogenes* from intracellular vacuoles precipitates intracellular growth and actin polymerization [39,122]. Actin polymerization is important in the cell-to-cell transfer of *L. monocytogenes* and is mediated by the ActA product of the *actA* gene [123]. A surface protein, ActA causes host cell actin to assemble into filaments around the bacterium. After 2 or 3 hours, the actin filaments polarize at one end of the organism. This "comet tail" provides propulsive force for the organism to move through the cytoplasm. When the bacterium reaches the cell membrane, it forms a filipod that is ingested by adjacent cells. In the process, the organism avoids exposure to the extracellular environment. In addition to hepatocytes, enterocytes, and phagocytic cells, *Listeria* can grow and spread in fibroblasts, epithelial cells, vascular endothelial cells, and renal tubular epithelial cells [122].

There is normally a decrease in viable bacteria within the monocyte/macrophage phagocytic system 3 to 4 days after infection begins. This decrease heralds the onset of the T cell–dependent stage of anti-*Listeria* defense and the beginning of acquired resistance [124–126]. Development of cellular immunity against *Listeria* peaks at 5 to 8 days of infection and can be shown by adoptive transfer of resistance using immune T cells [126]. At this stage, the number of activated macrophages in infected tissue rapidly increases (Fig. 13–2).

## Cellular Response

For adult animals, the process leading to acquired immunity to *Listeria* has been partially elucidated, and the sequence of cell-to-cell interaction resulting in cytolytic activity is becoming clear. In adult immunocompetent animals, *Listeria* are phagocytosed by "professional" phagocytes (macrophages and monocytes) and by "nonprofessional" phagocytic cells (e.g., fibroblasts, hepatocytes) (see Fig. 13–1). When ingested, partial degradation of *Listeria* occurs, and transfer of the *Listeria* protein antigen fragments to the macrophage cell surface takes place [127].

Peptides resulting from digestion of *Listeria* in the cytoplasm are actively processed by the endoplasmic reticulum, where they bind to major histocompatibility complex (MHC) class I molecules (Fig. 13–3) [127]. The *Listeria*-peptide-MHC complex is transported to the cell surface where it can be recognized by cytolytic T lymphocytes (CD8 phenotype).

Bacterial peptides that are digested within phagosomes are transported to the plasma membrane, where they attach to MHC class II molecules. CD4 T lymphocytes recognize specific antigens that are presented by MHC class II membrane receptors [128]. Development of T helper ($T_H$) subset during an immune response is pivotal because *L. monocytogenes* infection is most effectively controlled through this immune response [128]. *L. monocytogenes* induction of $T_H1$ development in vitro is mediated by macrophage-produced interleukin (IL)-12. Cells with $T_H1$ phenotype secrete IL-2 and interferon (IFN)-$\gamma$ during primary infection [129,130]. Although a few $T_H2$ cells may develop during *Listeria* infection, they play little role in the clearance of the pathogen [131].

In the presence of *Listeria* antigens and IL-2, T cells divide, producing *Listeria*-specific clones. In vitro evidence shows that immune CD8 T cells are cytolytic for *Listeria*-infected macrophages and hepatocytes (see Fig. 13–3) [132,133]. A robust CD8 T-cell response is induced during *L. monocytogenes* infection. *Listeria*-specific CD8 T cells confer protective immunity to naïve animals in adoptive transfer experiments; however, these T cells lose antibacterial activity within days [134]. Neutrophils and monocytes that migrate to the site of primary infection may participate in the lysis of infected cells, but, more importantly, play a role in the elimination of bacteria that are released to the surrounding tissue. By this stage of infection, phagocytic cells have been primed or activated by IFN-$\gamma$ or cytokines, making them more effective killers [134–140].

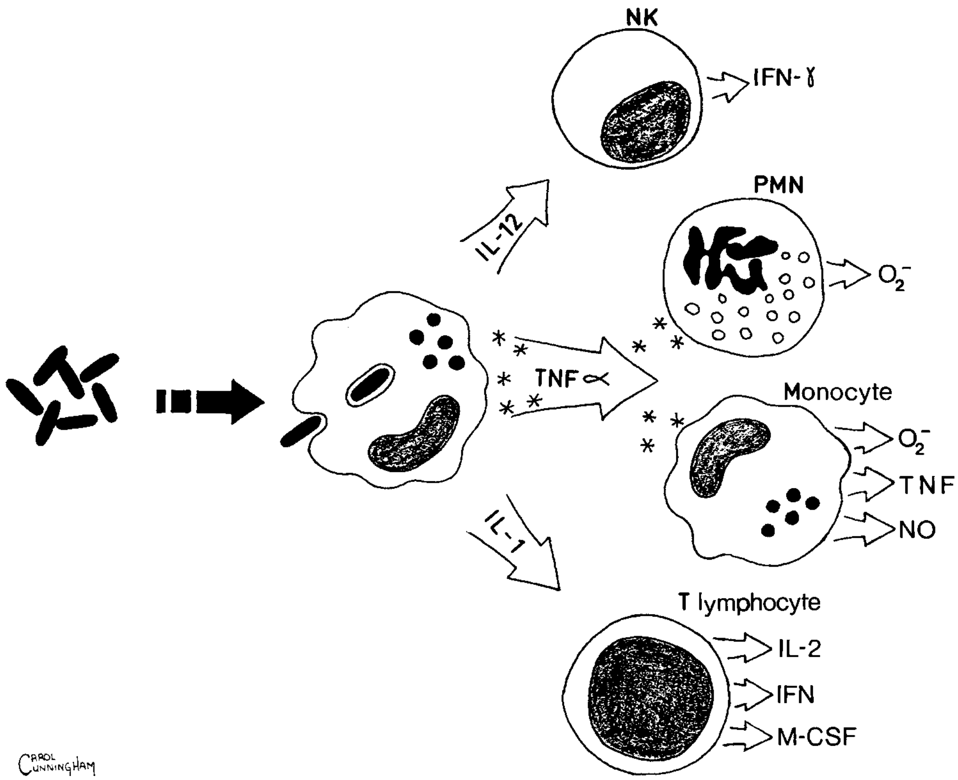

**FIGURE 13–2 Interferon (IFN) and cytokine production.** Blood monocytes and tissue macrophages produce various cytokines after ingestion of live *Listeria* organisms. Interleukin (IL)-12 causes activation of natural killer (NK) cells, which release high concentrations of IFN-γ. Tumor necrosis factor (TNF)-α is produced in large concentrations by monocytes and macrophages after ingestion of *Listeria* organisms TNF-α leads to priming of polymorphonuclear leukocytes and activation of other macrophage cells, with increased production of superoxide ($O_2^-$), nitric oxide (NO), and TNF-α. Macrophage-produced IL-1 leads to proliferation of T cells, which produce immunomodulating proteins such as IL-2, macrophage colony-stimulating factor (M-CSF), and IFN-γ.

## Role of Toll-like Receptors, Interferon, and Cytokines

Toll-like receptors (TLRs) are conserved primitive membrane proteins found in cells that have been identified more recently as key to initiation of innate immunity [141]. At present, 10 TLRs have been identified. TLR2 and TLR6 are heterodimers for gram-positive peptidoglycan. Surface TLRs stimulate an innate immune response through a signaling pathway involving intracellular kinases and transcription factors. The first intracellular adapter molecule in this cascade is myeloid differentiation antigen 88 (MyD88), which functions as a crucial first adapter protein of several TLRs, including TLR2 and TLR6 [142]. The role of the TLR pathway in innate immunity to *Listeria* has become clear in recent years [36]. TLR2-deficient mice show partial impairment in their resistance to *Listeria* [143]. MyD88 subserves multiple TLRs, however, and has an even more crucial role in early clearance of *Listeria* and cytokine signaling [143–145].

In mature immunocompetent animals, *Listeria* infection induces circulating IFN-γ and IFN-α/β on the 2nd or 3rd day in the acquired phase of immunity. Cytokines such as macrophage colony-stimulating factor (M-CSF) [131] and tumor necrosis factor (TNF)-α also appear during the first 5 days and have been implicated as mediators of *Listeria* clearance [139,146–151]. Peak immunity to *Listeria* is expressed about the 6th day of infection, which coincides with maximal $T_H1$ cell synthesis of IFN-γ [152,153]. A role for endogenous IFN-γ in resolution of *L. monocytogenes* infection has been shown [154,155]. Adult animals treated with monoclonal antibody directed against IFN-γ do not develop activated macrophages, and clearance of *Listeria* from liver and spleen is decreased [154].

The cytokine cascade involving various interleukins, IFN, and TNF-α is essential for host response to *Listeria* infection. MyD88-initiated signaling pathways are required for IL-1, IL-12, IL-18, and TNF-α induction in monocytes and other early responsive cells [143,156–159]. All of these cytokines are involved in an early response to *Listeria* infection through their activation of resident macrophage cells, circulating monocytes, and polymorphonuclear neutrophils (PMNs). Activation of dendritic cells in a TLR-dependent fashion leads to early removal of 90% of the bacterial burden in the liver within 6 hours of *Listeria* infection and may represent a critical link between the innate and adaptive immune processes [159,160].

TNF-α is a key cytokine to enhance antibacterial or antiparasitic resistance mechanisms (see Fig. 13–2) [161–164]. Many cell types produce TNF-α, including natural killer (NK) cells [165]; however, monocytes and macrophages are probably the most abundant source. Endotoxin (lipopolysaccharide) and other agents, including mitogens; viruses; protozoa; and cytokines such as M-CSF, IL-1, IL-2, and IFN-γ, have been identified as inducers of TNF-α [166–169]. When administered before infection, TNF-α–inducing agents enhanced resistance of the host to bacterial infection [170].

Endogenously produced TNF-α during sublethal *Listeria* infection in adult animals seems to function as an inducer of resistance [146,148]. Injection of mice with anti–TNF-α immunoglobulin results in a striking proliferation of bacteria during the first 2 to 3 days of infection; however, administration of anti–TNF-α immunoglobulin

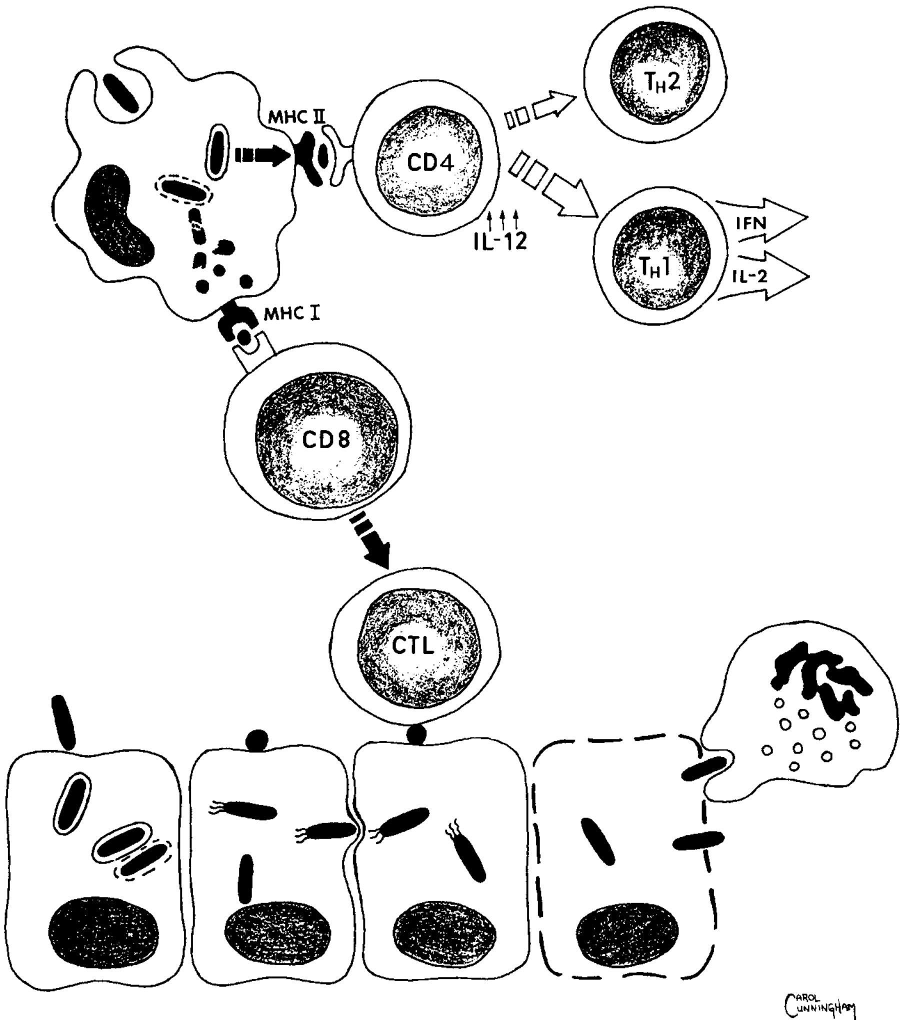

**FIGURE 13–3 Activation of cytolytic cell mechanisms.** Within an antigen-presenting cell, organisms killed and digested within a phagosome release bacterial peptides that are transported to the plasma membrane, where they attach to major histocompatibility complex (MHC) class II molecules. CD4 T lymphocytes recognize specific antigens that are presented by MHC class II receptors. CD4 T lymphocytes differentiate predominantly into $T_H1$ cells through stimulation by interleukin (IL)-12. $T_H1$ cells secrete high concentrations of IL-2 and interferon (IFN)-γ during primary infection. Bacterial peptides may also come from proteolytic digestion of intracytoplasmic organisms. Bacterial peptides are processed by the endoplasmic reticulum where they bind to MHC class I receptors. The bacterial–peptide–MHC I complex is transported to the cell membrane, where it is recognized by cytolytic T lymphocytes (CD8 phenotype). These cells cause lysis of *Listeria*-infected cells, which are recognized by the presence of listerial peptides on their surface. Lysis of *Listeria*-infected cells leaves the organism exposed to phagocytosis and killing by activated phagocytic cells, polymorphonuclear leukocytes, and monocytes.

on day 5 of infection has virtually no effect on *Listeria* replication in the spleen and liver [139,140,148]. These results suggest that TNF-α–dependent mechanisms limit intracellular infection early in the course of infection. Localized production of TNF is shown in supernatants of organ homogenates from the liver or spleen [171].

IL-12 participates in the differentiation of $T_H1$ cells, IFN-γ production, and NK cell activation [128,151,172]. In the absence of $T_H1$ activation, animals are more susceptible to *L. monocytogenes* infection [128,172]. IL-1, IL-12, and more recently IL-18, molecules whose receptor signaling requires MyD88, all are required for normal host defense against *Listeria* [144,160,173].

## HOST RESPONSE IN NEONATES

### Cell Activation

In fetal and newborn animals, susceptibility to *Listeria* seems to be associated with delayed activation of macrophages [174,175]. Studies on the afferent and efferent arms of cell-mediated immunity in fetal and newborn mice have shown that macrophage and T-lymphocyte interaction and macrophage activation is impaired [171,176–181].

Suppression of cell-mediated immunity during pregnancy is necessary to prevent fetal rejection. Cell-mediated immunity is essential, however, to combat intracellular pathogens, and the human placenta is extremely sensitive to microbial invasion by such organisms. After invasion, *Listeria* grows rapidly in the placenta and the fetus. Until more recently, very little was known about the molecular mechanisms responsible for transmission of pathogens across the fetal-placental barrier. A better understanding of species variability in placenta immunology and physiology and cell receptors for *Listeria* has provided insights into the vertical transmission of infection.

Because of similarities between the human and guinea pig placenta, it has been proposed as an animal model to study human fetal infection [182]. The InlA–E-cadherin interaction that facilitates bacteria crossing cellular barriers is exploited by *Listeria* in fetal infection [110]. E-cadherin is present in human and guinea pig placentas. ActA on the surface of *Listeria* is also required to cross the fetal-placental barrier, by enabling cell-to-cell spreading [183]. In the rhesus model, animals exposed to *L. monocytogenes* at the beginning of the third trimester had increased risk of stillbirth delivery and showed pathology similar to

humans [184]. Antibody and *Listeria*-induced cell proliferation was increased in mothers after delivery of stillborn rhesus monkey infants. The relevance of animal studies to human infection remains to be determined; however, similar immune responses are found among mothers and infants surviving natural *Listeria* infection [185].

NK cells also seem to be important in early response to *L. monocytogenes* infection. The proportion of mononuclear cells expressing NK cell phenotype and NK cell activity is decreased at birth, particularly in premature infants [186,187]. NK cell phenotype and function increase rapidly in the weeks after birth.

### Toll-like Receptors, Interferon, and Cytokines in Newborns

In adult animals and adult-derived cells, *Listeria* infection induces IL-12 and IL-18 production, which mediates $T_H1$ differentiation, NK cell activation, and IFN-α production [114]. The major cellular source of IL-12 and IL-18 are monocytes, macrophages, and dendritic cells. After lipopolysaccharide stimulation, IL-12 messenger RNA (mRNA) expression and protein production in cord blood mononuclear cells is also greatly decreased compared with adult cells [188]. In addition, the half-life of IL-12 p40 mRNA is shortened in activated cord blood cells compared with adult cells [189]. Cord blood mononuclear cells from humans are capable of responding in vitro to exogenous IL-12 in high concentrations, however.

In adult animals, IFN and agents that induce or augment IFN production confer protection against lethal listeriosis [190,191]. Synthesis of IFN-γ, IL-2, and IL-4, all of which modulate the immune response and macrophage activation, is deficient in newborns [181,192–194]. Although production of these factors may be defective, newborn animals do respond to exogenous IFN-γ; pretreatment with IFN-γ or its inducers [195] protects against subsequent infection.

The ontogeny of cytokine-related host defense mechanisms has not been studied in depth. TNF-α is decreased in newborn rats infected with *L. monocytogenes* [171]. In one study of *L. monocytogenes*–infected newborn rats, TNF-α was detected only in animals older than 8 days of age. The age at which TNF-α is measurable corresponds to the approximate age at which increased resistance to *L. monocytogenes* is seen. In addition, the study showed that IFN-γ may enhance resistance to *L. monocytogenes* in newborn animals by permitting them to respond to exogenous TNF-α.

The pattern of delayed or diminished cytokine response in human newborns is similar to the response in animals deficient in TLRs. This possibility has been explored in human newborns. TLR-2 and TLR-4 expression is normal on mononuclear and PMN cells of newborns [157]. It is now known that TLRs require membrane-associated proteins to initiate intracellular messenger activation and cytokine secretion. Chief among these proteins is MyD88, an intracellular myeloid differentiating antigen needed for intracellular signaling of all TLR proteins. In human newborn cells, diminished TNF-α secretion by stimulated monocytes and diminished superoxide production by PMNs are associated with diminished intracellular MyD88 [157,196]. The control of *L. monocytogenes* infection depends on rapid activation of the innate immune system through TLR-2 and MyD88, since animals deficient in either succumb to *Listeria* infection [315].

### Serum Factors

Opsonic activity of newborn serum for *Listeria* is minimal [197,198]. *Listeria* is opsonized primarily by IgM together with the classic complement pathway. Because newborn serum has negligible amounts of IgM and low concentrations of the classic complement pathway, its poor opsonic activity may contribute to the severity of infection in newborns. Adult serum may also contain specific antibodies to inhibit *L. monocytogenes* invasion of brain microvascular endothelial cells [199]. The inhibitory antibody, which is absent in newborn cord serum, reacts with the *Listeria* surface protein InlB, described earlier as a key virulence factor.

## PATHOLOGY

Histologically, human listeriosis is characterized by miliary granulomas and focal necroses or by suppuration. The term *listerioma* has been coined for *Listeria*-associated granulomas. In the newborn, *Listeria* infection of organs produces multiple, tiny nodules that are visible on gross examination [200]. Massive involvement of the liver is typical, reflecting the abundance of internalin receptors on hepatocytes [201]. Often, as in miliary tuberculosis, the liver is seeded with grayish yellow nodules. Analogous findings are observed in the spleen, adrenal glands, lungs, esophagus, posterior pharyngeal wall, and tonsils. Subepithelial granulomas often undergo necrosis. Focal granulomas may also be detected in the lymph nodes, thymus, bone marrow, myocardium, testes, and skeletal muscles. The intestinal tract is affected to a variable degree, with a preference for the lymphatic structures of the small intestine and appendix. Cutaneous lesions of neonatal listeriosis were first described by Reiss [202] and occur most commonly on the back and lumbar region (Fig. 13–4).

Granuloma formation is also typical in listeriosis of the central nervous system (CNS) [203]. A characteristic histologic picture is seen in *Listeria* encephalitis, consisting of cerebral tissue necrosis with a loosening of the reticulum and an infiltration of leukocytes and lymphocytes leading to abscess formation.

Suppurative inflammation is the second form of tissue reaction to listeriosis. It is predominantly found in the meninges, conjunctivae, and epithelial linings of the middle ear and nasal sinuses. In meningitis, the subarachnoid space becomes filled with thick purulent exudate.

The histologic changes in human listeriosis are the same as the changes observed in animals. The organisms cause necrosis, followed by a proliferation of reticuloendothelial cells, resulting in the development of granulomas. The center of the granuloma is necrotic, and the periphery contains an abundance of chronic inflammatory cells. *Listeria* organisms are present in variable numbers within these necrotic foci and can be shown with a Gram stain or Levaditi silver impregnation. Similar changes are found in all affected organs, independent of the age of the infected individual.

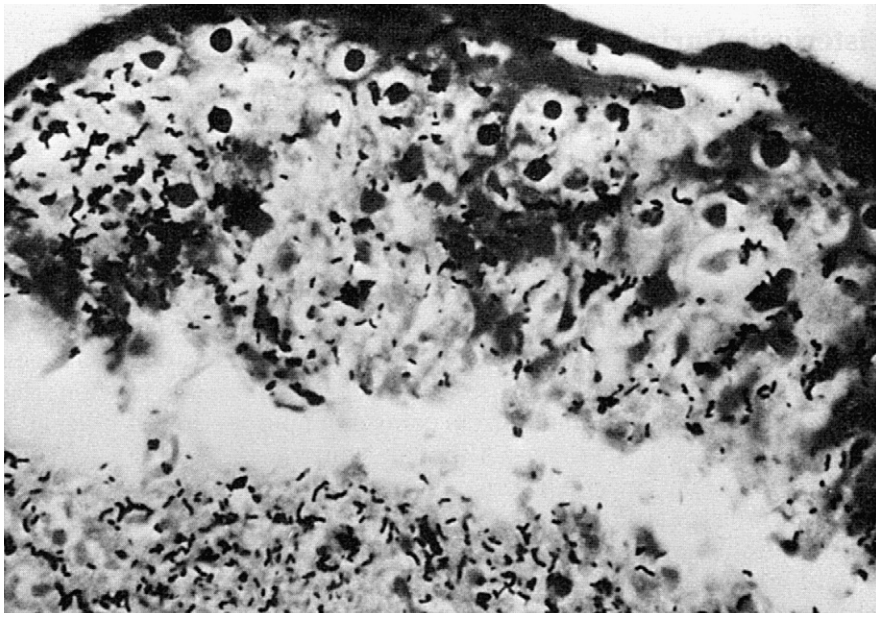

**FIGURE 13–4 Cutaneous listeriosis.** Note the numerous gram-positive rods that extend from the dermis below into the epidermis above.

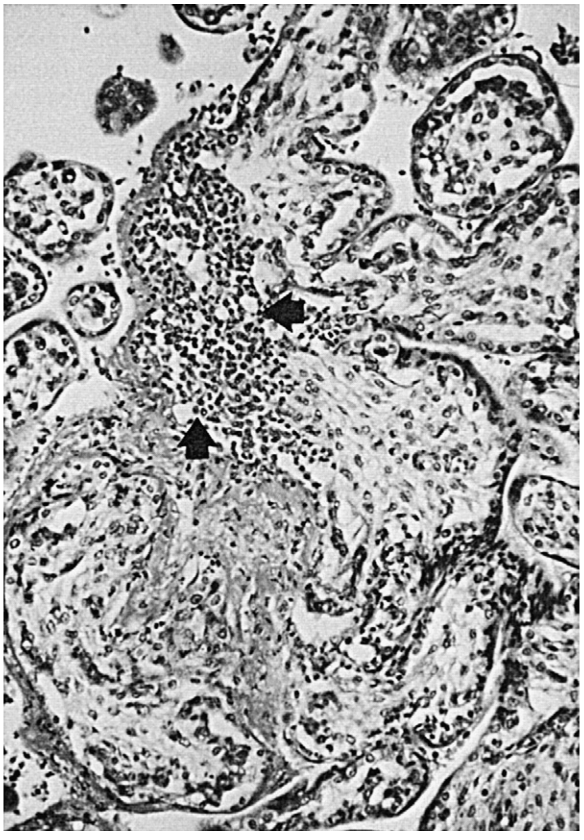

**FIGURE 13–5 *Listeria* placentitis.** Note the microabscess between the necrotic villous trophoblast and the stroma (*arrows*). Chorionic villi are enmeshed by intervillous and inflammatory material.

The gross and microscopic appearance of the placenta in listeriosis, although not pathognomonic, is sufficiently distinct to enable a presumptive diagnosis by an experienced pathologist (Fig. 13–5). *Listeria* placentitis is characterized grossly by multiple minute, white or gray necrotic areas within the villous parenchyma and decidua; the largest areas tend to occur in basal villi and the decidua basalis [204–206]. These necrotic foci are macroabscesses identical to those described in other fetal organs [200]. Typically, localized collections of PMNs are found between the villous trophoblast and stroma, and inflamed or necrotic chorionic villi are enmeshed in intervillous inflammatory material and fibrin. Chorioamnionitis, deciduitis, villitis, and funisitis (in order of frequency) are seen. Cord lesions may be confined to superficial foci. Gram-positive rods are usually demonstrable within the necrotic centers of villous and decidual microabscesses and within the membranes and umbilical cord. An immunohistochemical stain using polyclonal antibody directed at LLO has also been used for pathologic identification [207].

## CLINICAL MANIFESTATIONS

The clinical features of listeriosis are variable and may mimic infection by other organisms or disease states. Five major clinical presentations are distinguishable.

### LISTERIOSIS DURING PREGNANCY

The predilection of *Listeria* for the placenta and fetus is well documented in humans [208–212]. Maternal listeriosis is usually transmitted to the fetus by the transplacental route. Although early gestational listeriosis may be undetected [213], clinically identified cases of perinatal listeriosis are easily identifiable after the 5th month of pregnancy, as stillbirth or septic fetuses.

Maternal flulike illness with fever and chills, fatigue, headache, and muscle pains often precedes delivery by 2 to 14 days. Although symptoms in the mother may subside before delivery, infection and fever precipitating delivery are common. Blood cultured from pregnant women can yield *Listeria*. Premature labor in pregnant women with listeriosis is common; length of gestation is

less than 35 weeks in approximately 70% of cases. The mortality rate, including stillbirth and abortion, is 40% to 50%. Early treatment of *Listeria* sepsis in pregnancy can prevent infection and sequelae in the fetus and newborn [214,215]. At the time of delivery, maternal symptoms of infection may be pronounced; however, symptoms in the mother usually subside with or without antibiotic treatment soon after delivery.

The pathogenesis of fetal listeriosis is unclear. Because the heaviest foci for neonatal infection are lung and gut, the fetus is probably infected by swallowing contaminated amniotic fluid after placental infection is established. An ascending pathway from the lower genital tract is rare. *L. monocytogenes* chorioamnionitis diagnosed by transabdominal amniocentesis before membrane rupture has been reported and supports a blood-borne route of infection [200,210,215,216]. Placental chorionic vascular thrombi can be associated with maternal coagulopathy. Emboli originating from *Listeria*-infected placental vessels have been described as a cause of congenital stroke in an infant [207].

Susceptibility to *L. monocytogenes* is markedly increased in pregnant animals [181,182,217–219]. Immunoregulation during pregnancy is poorly understood. The placenta constitutes a unique immunologic site because suppression of the local cellular immune response is required to protect the fetus from immunologic rejection [212,220,221]. As a result, infection with intracellular organisms can lead to overwhelming proliferation and disease.

## EARLY-ONSET NEONATAL LISTERIOSIS

The first descriptions of neonatal listeriosis were published in the 1930s by Burn [222–224]. Since then, neonatal infection has been recognized as the most common clinical form of human listeriosis. Similar to group B streptococcal infection, neonatal listeriosis is divided into two clinical forms defined by age: early-onset (≤1 week of age) and late-onset (>1 week of age) infection. Clinical and laboratory manifestations of neonatal listeriosis are outlined in Table 13–2, based on clinical cases in which early and late forms of the disease could be differentiated.*

*References [78,85,90,102,208,216,225–230].

**TABLE 13–2** Clinical and Laboratory Findings of Early-Onset and Late-Onset Neonatal Listeriosis

| | Maternal Perinatal Illness (%) | |
|---|---|---|
| **Feature** | **Early Onset*** | **Late Onset†** |
| Mortality (%) | 25 | 15 |
| Median age in days (range) | 1 (0-6) | 14 (7-35) |
| Male (%) | 60 | 67 |
| Preterm (%) | 65 | 20 |
| Respiratory involvement (%) | 50 | 10 |
| Meningitis (%) | 25 | 95 |
| Blood isolate (%) | 75 | 20 |
| Maternal perinatal illness (%) | 50 | 0 |

**Data from references [81, 86, 204, 212, 221–225].*
*†Data from references [74, 98, 221, 225, 226].*

Classically, early-onset neonatal listeriosis develops within 1 or 2 days of life. Nosocomial transmission is also documented. In one outbreak, nine infants developed nosocomial listeriosis, after being bathed with *L. monocytogenes*–contaminated mineral oil shortly after birth [108]. Contamination of the multidose container occurred with its use on an infant with early-onset listeriosis. Clinical signs of infection developed 4 to 8 days later and were similar to signs seen in late-onset infection (insidious onset of illness with fever and meningitis was common).

Evidence of preceding maternal illness is often described in infants with early-onset disease. Although some maternal symptoms are vague and nonspecific (e.g., malaise, myalgias), others are sufficiently distinctive (i.e., fever, chills) to alert physicians to the risk of prenatally acquired listeriosis. Blood cultures from such mothers are often positive for *Listeria*.

Although early-onset disease may occur in neonates 7 days of age, most cases are clinically apparent at delivery and show meconium staining, cyanosis, apnea, respiratory distress, and pneumonia. Meconium-stained amniotic fluid is a common feature in such infants and may occur at any gestational age. Pneumonia is also common, but radiographic features are nonspecific (peribronchial to widespread infiltration). In long-standing infection, a coarse, mottled, or nodular pattern has been described. Assisted ventilation is frequently necessary in these infants. Persistent hypoxia despite ventilator assistance is seen in severely affected infants.

In severe infection, a granulomatous rash—granulomatosis infantisepticum—has been described (Fig. 13–6). Slightly elevated pale patches (1 to 2 mm in diameter) with a bright erythematous base are seen. Biopsy specimens of these areas show leukocytic infiltrates with multiple bacteria present (see Fig. 13–4).

Laboratory features are nonspecific; a leukocytosis with presence of immature cells may be seen, or neutropenia is noted with severe infection. Thrombocytopenia may also occur [208,226]. Many infants are anemic. These laboratory and clinical features fail to distinguish listeriosis from group B streptococcal or other severe early-onset bacterial infections. The association of early-onset listeriosis with prematurity and maternal infection suggests the presence of intrauterine infection. The frequent presence of chorioamnionitis in the absence of ruptured membranes [85,229] supports the hypothesis of *Listeria* infection occurring by a transplacental route, which differs from the common route of group B streptococcal acquisition via aspiration of contaminated vaginal or amniotic fluids.

## LATE-ONSET NEONATAL LISTERIOSIS

Neonatal *Listeria* infection that occurs after 7 days of life is considered late-onset infection. Although there is some overlap between early-onset and late-onset forms of listeriosis, the clinical patterns are usually distinct. Common clinical and laboratory features of late-onset neonatal listeriosis are presented in Table 13–2. The most common form of *Listeria* infection during this period is meningitis, which is present in 94% of late-onset cases. In many centers, *Listeria* ranks second only to group B *Streptococcus* as a cause of bacterial meningitis in this age group, causing approximately 20% of such infection [225].

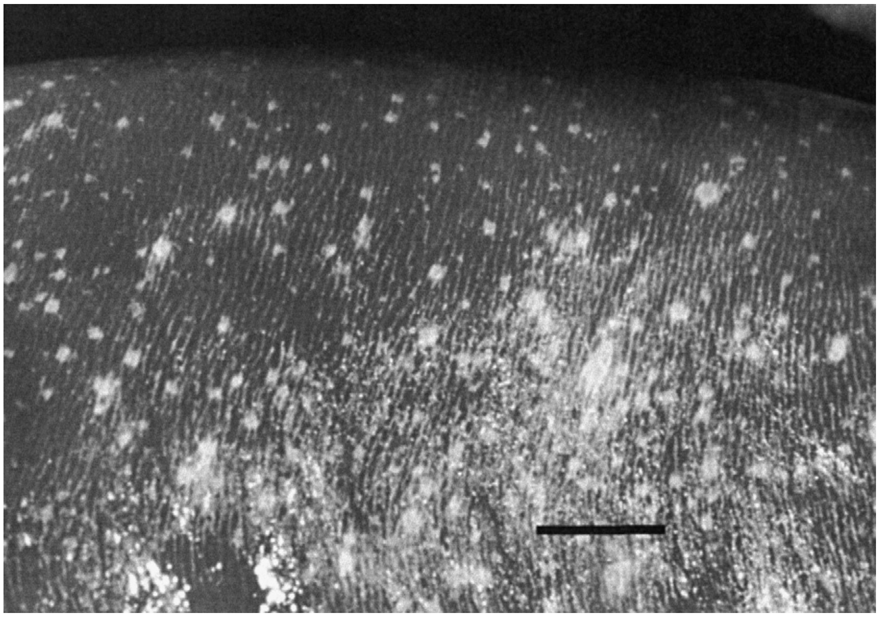

**FIGURE 13–6 Rash of neonatal *Listeria monocytogenes* infection.** Areas of small, elevated pale pustules surrounded by a deep red erythematous base seen on the abdomen of a premature neonate (*horizontal bar* = approximately 1 cm in length).

Clinical features do not distinguish listerial meningitis in this age group from meningitis with other causes. A striking predominance of boys has been noted in most series. Fever and irritability are predominant clinical features. Often, infants do not appear excessively ill and may elude diagnosis for several days. Other clinical forms of disease at this age are less common, but include *Listeria*-induced colitis with associated diarrhea and sepsis without meningitis [231,232].

Laboratory features of late-onset infection are nonspecific as well. Cell counts in cerebrospinal fluid are usually high, with a predominance of neutrophils and band forms. Occasionally in long-standing disease, numerous monocytes may be seen. Gram stain of cerebrospinal fluid may not always suggest a diagnosis because the organism may be in rare abundance or the morphology can be atypical, or both. Variable decolorization during staining may result in organisms appearing as gram-negative rods or gram-positive cocci. The appearance of organisms as illustrated in Figure 13–7 is characteristic of listeriosis in the early phase of severe meningitis. Mortality of late-onset newborn infection is generally low, unless diagnosis is delayed by more than 3 or 4 days after onset. Long-term sequelae and morbidity are uncommon.

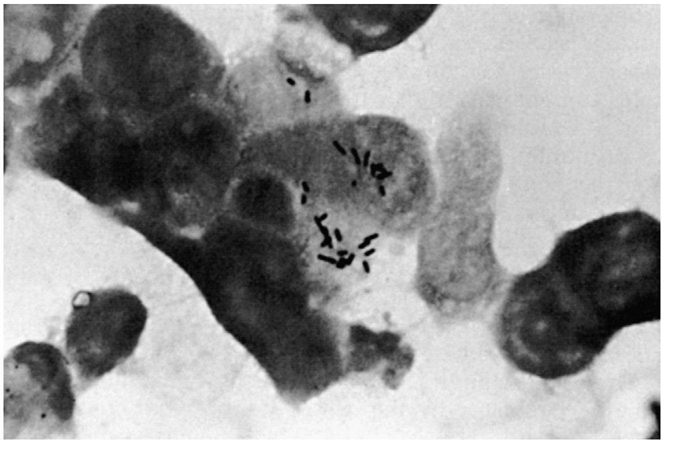

**FIGURE 13–7** Short, gram-positive intracellular organisms with variable length and rounded ends are arranged irregularly.

## CENTRAL NERVOUS SYSTEM INFECTION (ADULTS)

In many developed countries, *Listeria* has become the third most frequent cause of meningitis in adults, after *Streptococcus pneumoniae* and *Neisseria meningitidis*. A prospective nationwide study examined risk factors and clinical features of *Listeria* meningitis [233]. In 30 cases studied, every patient was either immunocompromised or older than 50 years of age. Clinical features (in contrast to prior atypical descriptions from retrospective studies) were indistinguishable from other causes of community-acquired bacterial meningitis. Almost all patients had at least two of the four classic symptoms of fever, headache, neck stiffness, and altered mental status. Congruent with prior reports, onset was subacute in a significant proportion (27%) of cases. Rhombencephalitis with ataxia, cranial nerve palsies, and multiple microabscesses on magnetic resonance imaging (MRI) or computed tomography (CT) is well described as a *Listeria* presentation in humans, as it is in ruminants ("circling disease") [203,234]. Survival of *Listeria* in the CNS is probably helped through cell-to-cell spread of the organism [235]. Morbidity and mortality are high in CNS infection, particularly if brainstem encephalitis is present [90,234,236].

## BACTEREMIA

In immunocompromised patients, bacteremia is the most common manifestation of *Listeria* infection, with meningitis second in frequency [77]. Clinical signs are indistinguishable from bacteremia caused by other organisms and typically include fever and myalgias after a prodromal

illness of nausea and diarrhea. The risk of invasive listeriosis in patients treated with antibody to TNF-α, with a malignancy, with HIV infection, or after organ transplant may be 1000 times the risk of otherwise healthy persons [85,237,238]. During the bacteremic phase, accompanying conjunctivitis is sometimes observed. Anton eye test [239] actually resulted from a laboratory accident in which a technician contaminated his face.

## OTHER CLINICAL FORMS OF INFECTION

A febrile gastroenteritis syndrome is now well recognized in adults and children. Disease appears sporadically, but at least seven outbreaks have been reported [240]. Although symptoms overlap considerably, children are more likely to have fever and vomiting, whereas adults typically have arthromyalgias and nonbloody diarrhea. Other symptoms include sore throat and profound fatigue. After ingestion of contaminated foodstuffs, incubation is usually less than 24 hours, but has ranged from 6 hours to 10 days. Processed meats have been repeatedly implicated [241], but other outbreaks have involved contaminated shrimp salad [242], rice salad [243], and chocolate milk [232]. The largest outbreak, in Italy, affected more than 1500 people [244]. Only a few patients developed invasive disease (sepsis) in these outbreaks, and the level of *Listeria* contamination apparently was very high [245].

Papular cutaneous lesions are often observed in newborns when listeriosis is disseminated. These lesions are to be distinguished from the primary skin lesions caused by *Listeria* as observed in adults [52,246], which are the result of direct contact, such as the handling of a cow's placenta after abortion by a veterinarian or farmer [53]. Other unusual forms of listeriosis, such as endocarditis [247,248], endophthalmitis [249,250], liver abscesses [201], peritonitis [251,252], osteomyelitis, and septic arthritis [238], have been described in adults, but are rare in infants.

# DIAGNOSIS

The clinical signs and symptoms of listeriosis overlap considerably with other illnesses, making a specific diagnosis difficult, if not impossible, when patients are first seen.

## SEROLOGY

The classic agglutination reaction (Widal test) shows antibodies against O and H antigens of the various *Listeria* serovars. Because of the antigenic complexity of *L. monocytogenes*, no agreement has been reached on the interpretation of agglutination reactions for diagnostic purposes.

Attempts to show complement-fixing *Listeria* antibodies date back to the 1930s [253]. In one study, serum samples collected from 32 mothers with perinatal *Listeria* infection were compared with 128 samples from matched controls [254]. The sensitivity and specificity of the complement fixation test were found to be 78% and 91%; however, the positive predictive value was only 75%. A titer of 1:8 or more is accepted as significant [234,255,256].

Detection of antibodies to LLO has also been used to diagnose human listeriosis [257]. Purified LLO incorporated into nitrocellulose filters is tested with serial dilutions of sera. Absorbed anti-LLO is identified using enzyme-labeled anti–human IgG. Sensitivity and specificity of the test are greater than 90%, and during a febrile gastroenteritis outbreak, it correlated well with clinical illness [232]. Although these results are impressive, the technique is not commercially available. A precipitin test [258], indirect hemagglutination reaction [259], and antigen fixation test [260] have also been described; these showed apparent success, but remain unavailable on a widespread basis.

## ISOLATION OF THE ORGANISM

Cultivation of *L. monocytogenes* is the gold standard of diagnosis. Culture of venous blood, ascitic and other fluids, cervical material, urine, placenta, amniotic fluid, lochia and meconium, and tissues at biopsy or autopsy offers the best chances for identifying *Listeria* in individuals with disease. Culture of the stool is not done routinely because feces are positive for *Listeria* in 1% to 5% of healthy women [55,261]. In an outbreak setting, stool culture with selective media may recover organisms for comparative typing (see "Organism").

Microscopic diagnosis may be attempted by use of Gram stain only in normally sterile specimens: cerebrospinal fluid, meconium, and tissue smears. The finding of short, sometimes coccoid, gram-positive rods strongly supports a suspicion of listeriosis and is indicative of this infection in meconium smears. Occasionally, *L. monocytogenes* may appear Gram positive or Gram negative or even predominantly coccoid. With long-standing disease or when the patient has received antibiotics, *Listeria* may appear gram-negative and be confused with *H. influenzae* when observed in the cerebrospinal fluid. In other instances, *Listeria* has been mistaken for pneumococci and corynebacteria.

## MOLECULAR DETECTION

Increasingly, PCR-based methods are used to detect *Listeria* in clinical samples such as cerebrospinal fluid [262,263]. PCR technology has progressed faster than regulatory standards, however, making quality assurance a significant issue with "home brew" molecular testing. Spurred by the food industry's demand for rapid and sensitive *Listeria* detection, approved kits for real-time PCR [264] and amplification with sequencing of *Listeria* 16S ribosomal RNA genes [265] are being adopted for food screening. The infrequent occurrence of clinical *Listeria* disease and the costly approval process for clinical diagnostic kits have resulted in limited availability of commercial diagnostic kits for clinical specimens.

# PROGNOSIS

Neonatal listeriosis accounts for the largest recognizable group of infections caused by *L. monocytogenes*. Fetal loss with early gestational infection is a recognized complication of maternal infection. In late gestational maternal infection, sparing of the fetus has been reported [266], but it is likely uncommon unless antepartum antibiotic treatment has been given to the mother [267,268].

Although fetal or neonatal infection with *L. monocytogenes* is known to have a high fatality rate, the long-term

morbidity is unclear. Rotheberg and associates [269] found an increased incidence of developmental delay assessed at a mean age of 29.5 months among small (<1250 g at birth), *Listeria*-infected infants who required assisted ventilation. Naege [270], studying children 4 to 7 years after they recovered from early-onset listeriosis, also found increased neurodevelopmental handicaps. Other authors have reported hydrocephalus [271].

In contrast, Evans and coworkers [272] found no evidence of neurodevelopmental sequelae in six of eight survivors studied at a mean age of 15 months and again at 32 months. The two infants with neurodevelopmental sequelae had severe acute perinatal sepsis with meningitis. Both had spastic diplegia. The authors concluded that long-term sequelae after neonatal early-onset listeriosis were uncommon. If meningitis is not present, the outcome may be generally good. The prognosis for infants with late-onset neonatal sepsis and meningitis has not been studied extensively.

# THERAPY

*Listeria* is susceptible to antibiotics commonly used in its treatment [253,273]. The high mortality rate and risk of relapse [254,274] have prompted a search for newer therapeutic regimens, however, including quinolones [275], trimethoprim-sulfamethoxazole [276,277], and rifampin [278]. Transferable plasmid-mediated antibiotic resistance has been reported [279] conferring resistance to chloramphenicol, tetracycline, and erythromycin.

## IN VITRO STUDIES

Susceptibility testing for *Listeria* has become more standardized with the publication of guidelines by the Clinical and Laboratory Standards Institute [280]. Until the late 1980s, clinical strains showed nearly universal susceptibility to ampicillin, penicillin, vancomycin, erythromycin, and tetracycline [281–283]. Since then, several reports have documented resistance to non–β-lactam antibiotics such as tetracycline and gentamicin [282,283]. Of more concern, penicillin and gentamicin resistance has been increasingly reported in environmental isolates from farms [284,285]. For many antibiotics, the minimal bactericidal concentration is often higher than clinically attainable levels, making them bacteriostatic, not bactericidal. Bactericidal antibiotics have a potential advantage for patients with impaired host defense mechanisms [286].

Studies with cephalosporin antibiotics have been consistently disappointing: The organism exhibits intrinsic high-level cephalosporin resistance [287]. Cephalosporins are incorporated into selective media (i.e., PALCAM agar) to inhibit other bacteria and enhance *Listeria* recovery [218]. Activity of newer fluoroquinolones against *L. monocytogenes* is promising [288,289]. One study found moxifloxacin to be the most effective antibiotic tested for eradication of the organism from the intracellular compartment [288].

## IN VIVO STUDIES

Several combinations of antibiotics [271,289–291] have been compared for their bactericidal activity against *L. monocytogenes* in vivo. Animal models have been a necessary way to assess therapeutic regimens, given the infrequency of human disease. Murine models employing normal adults [277,292], cortisone-treated adults [293], immunodeficient adults [294–296], and animals infected by inhalation of aerosolized *Listeria* [277] have been reported, and a rabbit meningitis model has been described [297,298]. The model most analogous to neonatal disease was described by Hawkins and colleagues [299]. In their study, neonatal rats received intraperitoneal inoculations and were randomly assigned to begin antibiotic regimens 2 days later.

Conflicting results complicate the interpretation of animal models. In addition to variable techniques (e.g., route of injection, bacterial strain, inoculum size), pharmacokinetic differences in various animal species must be considered. Rifampin metabolism differs widely among animal species [297,299,300], and the half-life of ampicillin is longer in human neonates than in most adult animals. In one study of adult mice infected with *L. monocytogenes*, no synergy was shown using ampicillin and gentamicin [301]. In the neonatal listeriosis model of Hawkins and colleagues [299], combining ampicillin and gentamicin was significantly better at eradicating organisms than ampicillin alone. Similarly, the combination trimethoprim-sulfamethoxazole was found to be superior to either drug alone [299]. In vivo studies of other antibiotics are also conflicting: Some authors have found rifampin to be highly active [277,300], whereas others have found it to be ineffective [302]. Strain variation may account for the widely discrepant results. In addition, rifampin monotherapy may lead to development of resistance. The use of ciprofloxacin in animal models has not suggested any therapeutic advantage over ampicillin [293,303]; however, moxifloxacin was equivalent to ampicillin plus gentamicin in an animal model [298].

## CLINICAL REPORTS

No prospective clinical trials for *L. monocytogenes* human infection have been reported. Anecdotal case reports or reviews after outbreaks generally support conclusions drawn from in vivo models. In one review of 119 cases of listeriosis from three centers in the United States, excellent therapeutic results were seen for patients treated empirically with penicillin or ampicillin; all had a reduction of fever and clinical improvement. Patients treated initially with cephalosporins had persistent fever and infection, however [303]. In the largest assessment of treatment regimens during a single outbreak [304], a lower mortality was reported for children given ampicillin (16% of 57 children) compared with children treated with chloramphenicol, tetracycline, or streptomycin (33% of 82 children). Trimethoprim-sulfamethoxazole has generally been used as second-line or alternative therapy in patients with significant β-lactam allergy. Case reports have also documented successful therapy of invasive infections with vancomycin [248,249]. Treatment failures and recurrent listeriosis are well described [254]. In some cases, weeks or months elapse between episodes. Two more recent studies looked at susceptibility profiles from clinical isolates over the past 50 years [305,306]. Both studies found that penicillin or ampicillin and gentamicin—the mainstay of therapy—remained predictably effective against *Listeria*.

## SUGGESTED MANAGEMENT

### Listeriosis during Pregnancy

If amnionitis is present, initial treatment should be given by the intravenous route to ensure adequate tissue levels (ampicillin, 4 to 6 g/day divided into four equal doses plus an aminoglycoside). If amnionitis is not present, or if acute symptoms of amnionitis have subsided, oral antibiotics are an option (amoxicillin, 1 to 2 g/day divided into three equal doses). In both situations, treatment should continue for 14 days. If the patient has a significant β-lactam allergy, therapeutic options are limited. Erythromycin may be given (the estolate form should be avoided because of increased liver toxicity during pregnancy), although there are no universal susceptibility guidelines for erythromycin and *Listeria*. Trimethoprim-sulfamethoxazole is an active agent, but theoretical risks of use in pregnancy must be balanced against potential benefits [307].

### Early-Onset Neonatal Listeriosis

Ampicillin in combination with an aminoglycoside is the preferred management for early-onset infection. For infants with body weight less than 2000 g, 100 mg/kg/day divided into two equal doses should be administered for the 1st week of life. For infants with body weight of more than 2000 g, 150 mg/kg/day divided into three equal doses should be administered for the 1st week of life. For the 2nd week of life, the appropriate dosages are 150 mg/kg/day and 200 mg/kg/day for infants weighing less than 2000 g body weight and more than 2000 g body weight respectively. Aminoglycoside doses vary with the agent chosen. For gentamicin, the suggested dosages are 5 mg/kg/day divided into two equal doses for the 1st week of life and 7.5 mg/kg/day divided into three equal doses for the 2nd week of life. For early-onset neonatal sepsis caused by *L. monocytogenes*, 10 to 14 days of treatment is recommended; however, a longer course of treatment should be given in the uncommon event of early-onset neonatal listeriosis with meningitis.

### Late-Onset Neonatal Listeriosis

Meningitis is commonly present in late-onset listeriosis. Delayed eradication of the organism may be seen in such cases. Ampicillin (200 to 400 mg/kg/day divided into four to six equal doses) in combination with an aminoglycoside is recommended. Lumbar puncture should be repeated in 48 to 72 hours to assess effectiveness of therapy. In the event of delayed clearance (>2 days), further investigations are indicated, including CT or cranial ultrasound to assess for the presence of cerebritis, brain abscess, or intracranial hemorrhage. If the organism remains present in the cerebrospinal fluid after several days, the addition of vancomycin, rifampin, or trimethoprim-sulfamethoxazole may be considered. Experience with such combination therapy for listeriosis in neonates is limited [308]. Cephalosporin antibiotics are not active against *Listeria*. Length of treatment is generally 14 to 21 days, depending on clinical course.

## PREVENTION AND OUTBREAK MANAGEMENT

Food-borne outbreaks of listeriosis are unpredictable and may occur in a wide geographic area. Reporting of all cases of listeriosis to public health authorities is important to identify outbreaks early. Case-control studies and environmental sampling are important aspects of outbreak investigations. Strains of *Listeria* from clinical and environmental isolates should be forwarded to a reference laboratory for appropriate epidemiologic typing. Serotyping and multifocus enzyme electrophoresis typing should be performed to characterize the epidemic strain.

During an outbreak of listeriosis, pregnant women presenting with sepsis syndrome or a flulike illness should be empirically treated with ampicillin and an aminoglycoside after appropriate cultures of blood, rectum, and vagina have been obtained. Amniocentesis for diagnosis of chorioamnionitis may be appropriate [309]. If membranes have ruptured and contamination is suspected, use of selective media may enhance the isolation of *Listeria* from these patients.

The recognition that sporadic cases of listeriosis are food-borne has prompted wide use of preventive guidelines by the CDC (Table 13–3) [60,310]. Guidelines for preventing listeriosis are similar to guidelines for preventing other food-borne illnesses and include thorough cooking of raw food from animals and thorough washing of vegetables and utensils. Persons at high risk, such as pregnant women, should also avoid soft cheeses and prepared salads, meats, and cheeses from deli counters.

**TABLE 13–3** Recommendations for Reducing the Risk of Listeriosis

| ***General Recommendations*** |
|---|
| Thoroughly cook raw food from animal sources (e.g., beef, pork, and poultry) |
| Wash raw vegetables thoroughly before eating |
| Keep uncooked meats separate from vegetables and from cooked foods and ready-to-eat foods |
| Avoid raw (unpasteurized) milk or foods made from unpasteurized milk |
| Wash hands, knives, and cutting boards after handling uncooked foods |
| Consume perishable and ready-to-eat foods as soon as possible |
| ***Additional Recommendations for High-Risk Groups*** |
| Do not eat hot dogs or ready-to-eat foods such as deli meats unless they are reheated until steaming hot |
| Wash hands after handling hot dogs and ready-to-eat foods |
| Do not eat soft cheeses (e.g., feta, Brie, and Camembert) or blue-veined cheeses unless they have labels that clearly state they are made from pasteurized milk |
| Do not eat refrigerated pâtés or meat spreads; canned or "shelf-stable" (pasteurized) pâtés and meat spreads may be eaten |
| Do not eat refrigerated smoked seafood unless it is contained in a cooked dish, such as a casserole; canned or shelf-stable smoked seafood may be eaten |

*Data from Lynch M, et al. Surveillance for foodborne-disease outbreaks—United States, 1998-2002. MMWR Surveill Summ 55:1-42, 2006; and Listeria Fact Sheet—Updated. Guelph, Ontario, University of Guelph Food Safety Network, 2003.*

One more recent study also implicated hummus and melons as a cause of sporadic *Listeria* illness [74]. Because of the severity of illness, pregnant women and others at risk may wish to add these to the list of foods to avoid. Thoroughly heating leftover foods until they are steaming hot has also been recommended [60]. Appreciation of the food guidelines by pregnant women is limited. Improved education of pregnant women regarding risk of listeriosis in pregnancy is needed [311,312]. A decrease in the rates of listeriosis in some geographic areas in the United States has been temporally associated with the publication of these guidelines and industry efforts directed at removing food-borne pathogens from the food chain [75,310,313].

CHAPTER 14

# STAPHYLOCOCCAL INFECTIONS

Victor Nizet ❂ John S. Bradley

## CHAPTER OUTLINE

Staphylococcal disease has been recognized in neonates for centuries; it was reported in 1773, when pemphigus neonatorum was described [1]. Outbreaks of staphylococcal disease in nurseries were first noted in the late 1920s [2], and the memorable term "cloud baby" was subsequently coined to describe index cases, often asymptomatic, who contaminated the nursery atmosphere with *Staphylococcus aureus* colonizing their respiratory tract, skin, or umbilical cord [3]. Until the late 1970s, staphylococcal disease in newborn infants was caused most often by *S. aureus* [4]. In recent decades, coagulase-negative staphylococci (CoNS) have assumed an equally important role, especially in premature infants in neonatal intensive care units (NICUs) [5–7], often responsible for 50% or more of all cases of clinically significant bacterial disease. Management of staphylococcal disease in infants has become increasingly more complicated, reflecting the increasing incidence of methicillin resistance and the threat of vancomycin resistance among isolates of *S. aureus* and CoNS. This chapter summarizes current information about *S. aureus* and CoNS and the diseases these organisms produce in newborns and young infants.

## EPIDEMIOLOGY AND TRANSMISSION

### *STAPHYLOCOCCUS AUREUS*

Many factors influence transmission of staphylococci among newborns, including nursery design, density of infant population, and obstetric and nursery practices. Other factors certain to influence transmission include virulence properties of the individual *S. aureus* strains and often poorly defined immunogenetic host factors. The complexity of isolating and investigating each variable in the epidemiologic equation accounts for the disagreement in the literature about which factors predominate in transmission and prevention of staphylococcal disease. A particular factor that is critical in one epidemic may not be a driving factor under different circumstances.

Quantitative culture studies show that very few *S. aureus* organisms are capable of initiating colonization in the newborn. Less than 10 bacteria can establish umbilical colonization in 50% of newborns, whereas approximately 250 organisms can achieve a similar effect on the nasal mucosa [8]. Colonization of the newborn umbilicus, nares, and skin occurs early in life. By the 5th day in the nursery, the colonization rate among nursery inhabitants

DOI: 10.1016/B978-1-4160-6400-8.00014-6

may be 90% [9]. The umbilicus or rectum usually is colonized before the nares [10,11].

These findings provide a plausible explanation for the challenge of defining any single factor in the environment (e.g., fomites, hands, clothes) as the ultimate source of infection. Nevertheless, most evidence indicates that the initial and perhaps major source of infection is medical and nursing personnel [8]. A strain of *S. aureus* common among medical attendants is far more likely than a maternal strain to colonize a given infant in the nursery [12]; in 85% of cases, infant colonization with *S. aureus* is likely to originate from an attendant's touch [13]. Persons with overt cutaneous lesions or disease often are highly infectious, but asymptomatic carriers can be infectious also [14], and carriage on the skin, in the anterior nares, and in the perineal area is relevant [15,16]. The frequency of intestinal carriage of the pathogen may be greatly underestimated as well [17].

Soon after the introduction of methicillin in 1960, methicillin-resistant *S. aureus* (MRSA) emerged as an important nosocomial pathogen [18]. For MRSA, resistance is mediated through the *mecA* gene, which codes for an altered penicillin-binding protein (called PBP2a) that has a dramatically reduced affinity for β-lactam antibiotics [19]. Beyond possessing *mecA*, MRSA isolates frequently harbor other antibiotic resistance determinants as well, limiting treatment options further. Risk factors for infection with MRSA include treatment with antimicrobials, prolonged hospitalization, and stay within an intensive care unit [20]. Since the mid-1990s, infection with community-acquired MRSA (CA-MRSA) isolates has been reported increasingly in patients without hospital contact or traditional risk factors for MRSA [21,22]. CA-MRSA strains typically have a distinct antibiotic susceptibility pattern and more frequently cause skin and soft tissue infections and necrotizing pneumonias compared with methicillin-sensitive *S. aureus* (MSSA). These isolates are readily transmitted between family members and close contacts [22].

The National Institute of Child Health and Human Development (NICHD) Neonatal Research Network reported that from 1998-2000, approximately 8% of initial episodes of late-onset sepsis among infants with very low birth weight (<1500 g) were caused by *S. aureus* [6]. More recently, Carey and colleagues [23] reported the epidemiology of MSSA and MRSA infections in the NICU at Columbia University Medical Center. During the study period, there were 123 infections caused by MSSA and 49 infections caused by MRSA. Overall, the clinical presentations and the crude mortality rates (16% to 17%) were similar in both groups, although infants with MRSA infections were significantly younger at clinical presentation than infants with MSSA infections. The most common manifestations were bacteremia (36%); skin, soft tissue, wound (31%); bacteremia plus skin and soft tissue (15%); endocarditis (7%); and rare cases of tracheitis, osteomyelitis, meningitis, or mediastinitis. The risk of developing MSSA or MRSA infection was inversely related to birth weight, with 53% of infections occurring in very low birth weight infants; most infections in infants weighing more than 2500 g were associated with surgical procedures. Reports of small outbreaks of CA-MRSA in NICUs and well-infant nurseries are appearing with increasing frequency [24–26].

When clusters of staphylococcal disease associated with hospital exposure occur, temporal clustering of cases suggests the possibility of an outbreak caused by a single strain [27]. In these situations, identity of the strain requires characterization based on a molecular technique, such as pulsed-field gel electrophoresis (PFGE) or multilocus sequence typing (MLST). MLST is a sequence-based typing system that uses the sequence of seven or more housekeeping genes to evaluate the genetic relatedness of strains of staphylococci [28]. The discriminatory power of this approach is less than that of PFGE, so the usefulness for the evaluation of local outbreaks is less [29]. Nevertheless, MLST allows the user to compare sequences from isolates of various locations through a central database (http://www.mlst.net).

## COAGULASE-NEGATIVE STAPHYLOCOCCI

CoNS are common inhabitants of human skin and mucous membranes. *Staphylococcus epidermidis* is the species found most commonly as a member of the normal flora of the nasal mucosa and the umbilicus of the newborn [30]. With sensitive culture techniques, the nose, umbilicus, and chest skin are found to be colonized with CoNS in 83% of neonates by 4 days of age [31]. Rates of colonization with *S. epidermidis* in one study of infants in a NICU were as follows: nose, 89%; throat, 84%; umbilicus, 90%; and stool, 86%; simultaneous percentages for *S. aureus* were 17%, 17%, 21%, and 10% [30]. Although most infants acquire CoNS from environmental sources, including hospital personnel, a small percentage are colonized by vertical transmission [32,33]. Isolates of *S. epidermidis* and other CoNS resistant to multiple antibiotic agents are common. In a study involving premature neonates, D'Angio and associates showed that the incidence of strains resistant to multiple antibiotics increased from 32% to 82% by the end of the 1st week of life [34].

The observation that CoNS are important nosocomial pathogens among newborns, especially low birth weight infants in NICUs, is explained by the prevalence of colonization with these organisms at multiple sites and the widespread use of invasive therapeutic modalities that subvert normal host epithelial barrier defenses. Examples of invasive treatments include endotracheal intubation, mechanical ventilation, placement of umbilical and other central venous catheters and ventriculoperitoneal shunts, and use of feeding tubes. In more recent epidemiology, CoNS account for more than half of bloodstream isolates obtained from neonates with late-onset sepsis [5–7].

An inverse relationship exists between the rate of infection with CoNS and birth weight and gestational age. Additional risk factors that are associated with CoNS bacteremia among very low birth weight neonates include respiratory distress syndrome, bronchopulmonary dysplasia, patent ductus arteriosus, severe intraventricular hemorrhage, and necrotizing enterocolitis [6].

Certain nutritional factors are associated with the development of late-onset sepsis, including delayed initiation of enteral feeding, prolonged period to reach full enteral feeding status, delayed reattainment of birth

weight, and prolonged parenteral hyperalimentation [6]. In a case-control study, administration of intralipids through a polytetrafluoroethylene (Teflon) catheter was also shown to be associated with an increased risk of bacteremia caused by CoNS [35]. Most experts believe the clinical and experimental data suggest that CoNS have not become more virulent over time. Rather, these ubiquitous organisms have become more common pathogens because therapeutic approaches have become increasingly invasive, and because very low birth weight premature infants, with compromised immunity, are surviving for longer periods.

## MICROBIOLOGY

Staphylococci are members of the family Staphylococcaceae and are nonmotile, non–spore-forming bacteria that are catalase-negative. Species of staphylococci are separated into two large groups on the basis of ability to produce the extracellular enzyme coagulase. Organisms that produce coagulase are known as coagulase-positive staphylococci, or *S. aureus* [36], and organisms that produce no coagulase are referred to as CoNS. The presence of coagulase can be evaluated either by assessing broth medium for secreted enzyme, which reacts with coagulase-reacting factor in plasma and results in formation of a fibrin clot, or by testing for cell-bound enzyme, which results in clumping when a suspension of organisms is incubated with plasma.

Staphylococci grow best in an aerobic environment, but are capable of growing under anaerobic conditions as well. They grow readily on most routine laboratory media, including Luria broth, and usually are isolated from clinical specimens using sheep blood agar. Gram staining reveals gram-positive cocci 0.7 to 1.2 mM in diameter that are usually visible in irregular grapelike clusters (Fig. 14–1A). Growth in liquid culture often results in a predominance of single cocci, pairs, tetrads, and chains of three or four cells. Dying organisms and bacteria in stationary phase or ingested by phagocytes may appear to be gram-negative. Growth on blood agar results in round, convex, shiny opaque colonies that are 1 to 2 mm in diameter after 24 hours of incubation. Colonies of *S. aureus* often are deep yellow or golden in color and typically are surrounded by a zone of β-hemolysis (Fig. 14–1B). By contrast, colonies of CoNS usually are chalk-white, often lacking surrounding hemolysis.

## *STAPHYLOCOCCUS AUREUS*

For clinical purposes, many of the key characteristics of *S. aureus* can be determined by simple procedures performed with commercial rapid identification kits and automated systems [36]. Historically, phage typing and serologic typing were the most common systems for differentiating strains of *S. aureus* for epidemiologic purposes [37]. In contemporary analysis, molecular approaches such as PFGE and MSLT have become the standard for defining strain identity in a patient with multiple isolates or in a possible outbreak involving multiple patients [38,39].

The staphylococcal cell wall is composed of two major components, peptidoglycan and teichoic acid [40,41]. *S. aureus* peptidoglycan is composed of chains of acetylglucosamine, acetylmuramic acid, alanine, glutamic acid, and lysine or diaminopimelic acid, with pentaglycine bridges that cross-link these chains. Four penicillin-binding proteins called PBP1, PBP2, PBP3, and PBP4 play an important role in peptidoglycan biosynthesis and are inactivated by β-lactams [42]. A mutated form of PBP2 (PBP2a) encoded by the *mecA* gene is the basis of methicillin resistance in the current epidemic of hospital-acquired MRSA (HA-MRSA) and CA-MRSA disease. Teichoic acid is a polymer of ribitol phosphate that is held in the cell wall by covalent attachment to the insoluble peptidoglycan. Staphylococcal teichoic acid is antigenic, and antibodies to this substance cause agglutination of isolated staphylococcal cell walls [43]. Antibodies to teichoic acid enhance opsonophagocytic killing of nonencapsulated strains of *S. aureus*, but have little effect on encapsulated isolates [44]. In contrast, antibodies to peptidoglycan play a key role in the opsonization of encapsulated *S. aureus* [45].

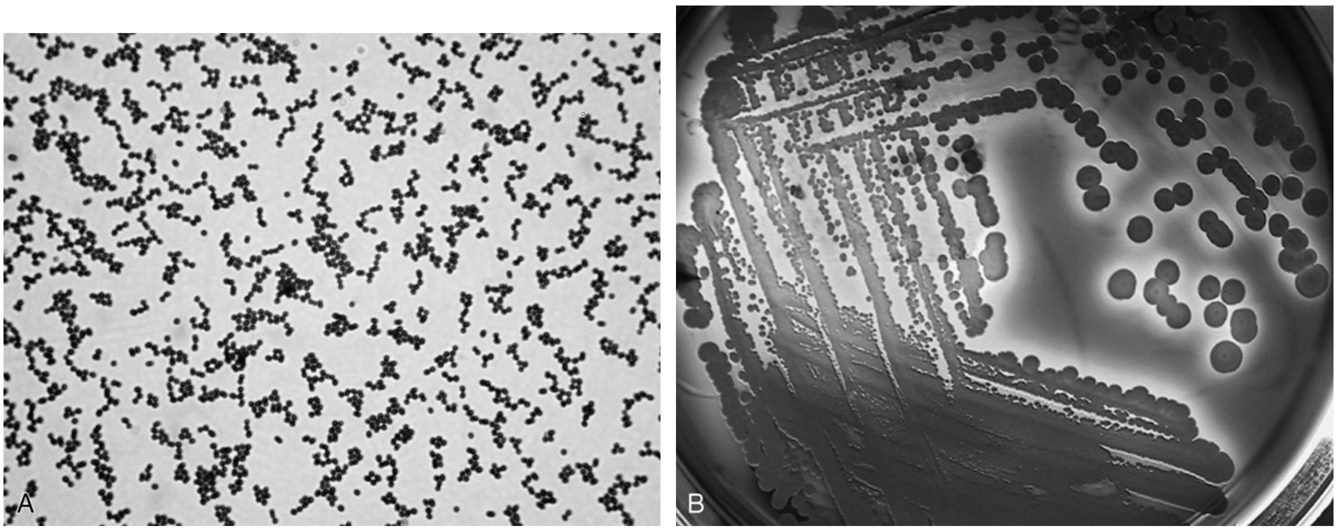

**FIGURE 14–1** **A**, Gram stain of *Staphylococcus aureus* showing characteristic clusters. **B**, Blood agar plate showing growth of *S. aureus* with zone of β-hemolysis surrounding colonies.

Antibodies to *S. aureus* teichoic acid and peptidoglycan are widespread in screens of the human population [45].

In addition to peptidoglycan and teichoic acid, other components of the *S. aureus* cell wall include the group antigen known as protein A, an immunoglobulin Fc binding protein, and numerous other surface-expressed proteins. Similar to the situation with other gram-positive bacteria, many *S. aureus* proteins anchored in the cell wall possess a carboxy-terminal LP(X)TG motif, which serves as a sorting signal for a membrane enzyme called sortase (SrtA) [46,47]. This enzyme cleaves polypeptides between the threonine and the glycine of the LP(X)TG motif and catalyzes formation of an amide bond between the carboxy group of threonine and the amino group of peptidoglycan cross-bridges [47]. These include several proteins involved in extracellular matrix binding and promoting *S. aureus* adherence to host epithelium [48].

*S. aureus* produces a polysaccharide capsular layer external to the cell wall. Capsular antigens are limited in antigenic specificity and highly conserved among clinical isolates, where the predominant capsules identified are serotype 5 and serotype 8 [49]. The serotype 5 *S. aureus* capsule has the structure (→4)-3-O-Ac-β-d-ManNAcA-(1→4)-α-l-FucNAc-(1→3)-β-d-FucNAc-$(1\rightarrow)_n$, whereas the serotype 8 capsule has the structure (→3)-4-O-Ac-β-d-ManNAcA-(1→3)-α-l-FucNAc-(1→3)-β-d-FucNAc-$(1\rightarrow)_n$ [50,51]. Although these two capsular polysaccharides differ only in the sugar linkages at the sites of *O*-acetylation of the mannosaminuronic acid residues, they remain serologically distinct. Capsule plays a role in the pathogen's resistance to phagocyte clearance.

Small colony variants of *S. aureus* isolated from clinical specimens have been recognized for nearly a century. Small colony variants have now been linked to persistent and relapsing *S. aureus* infections, including chronic osteomyelitis and soft tissue abscesses [52,53]. These phenotypes can be traced to biochemical defects in electron transport, which are associated with slow growth and reduced α-toxin production that promote survival and persistence within endothelial cells. It is hypothesized that the intercellular location represents a privileged niche against the actions of host innate defense molecules and antibiotics. Because they can be overlooked in the laboratory owing to their fastidious growth, extra efforts to identify small colony variants should be undertaken in the setting of persistent or relapsing *S. aureus* infection despite antibiotic therapy [52,53].

Nucleotide sequencing of the whole genome for several isolates of *S. aureus* [54,55], including MRSA strains [56,57], has established that the genome is 2.8 to 2.9 Mb in size, with approximately 2600 to 2700 open reading frames and an overall guanine-to-cytosine content of approximately 33% [54,55]. Much of the *S. aureus* genome seems to have been acquired by lateral gene transfer [56]. Most antibiotic resistance genes are carried on mobile genetic elements, including a unique resistance island. Pathogenicity islands belonging to at least three different classes have been identified, including toxic shock syndrome (TSS) toxin islands, exotoxin islands, and enterotoxin islands. The exotoxin and enterotoxin islands are closely linked to other gene clusters encoding putative virulence factors.

## COAGULASE-NEGATIVE STAPHYLOCOCCI

CoNS are a heterogeneous group of organisms that have been divided into 32 species [36]. The following 15 species of CoNS are found as members of the normal human flora: *S. epidermidis*, *Staphylococcus haemolyticus*, *Staphylococcus saprophyticus*, *Staphylococcus capitis*, *Staphylococcus warneri*, *Staphylococcus hominis*, *Staphylococcus xylosus*, *Staphylococcus cohnii*, *Staphylococcus simulans*, *Staphylococcus auricularis*, *Staphylococcus saccharolyticus*, *Staphylococcus caprae*, *Staphylococcus pasteuri*, *Staphylococcus lugdunensis*, and *Staphylococcus schleiferi* [36,58]. Among these species, several occupy very specific niches on the skin. *S. capitis* is most abundant on the head, where sebaceous glands are plentiful. *S. auricularis* has a striking predilection for the external auditory canal. *S. hominis* and *S. haemolyticus* are most common in the axillae and the pubic area, where apocrine glands are numerous.

Speciation of CoNS is accomplished on the basis of a series of biochemical characteristics, simplified in recent years by the commercial availability of miniaturized kits [36]. Differentiation of two strains belonging to the same species (subspeciation) represents a more difficult problem, however. Analogous to the situation with *S. aureus*, contemporary techniques for distinguishing strains of a given species include PFGE and MLST [59]. The composition of CoNS is quite similar to the makeup of *S. aureus* except that the teichoic acid contains glycerol in place of ribose, and the cell wall lacks protein A. Determination of the genome of *S. epidermidis* strain ATCC 12228 (a commensal isolate not associated with disease) revealed a genome approximately 2.5 Mb in size with 2419 open reading frames, greater than 10% smaller than the published genomes of *S. aureus* isolates [60]. Compared with the available *S. aureus* genomes, ATCC 12228 contains fewer antibiotic resistance genes and lacks pathogenicity islands and a capsule locus. A homologue of the *S. aureus srtA* gene is present, along with nine proteins predicted to contain an LP(X)TG motif.

# PATHOGENESIS OF DISEASE

## VIRULENCE MECHANISMS OF *STAPHYLOCOCCUS AUREUS*

The pathogenic process of *S. aureus* infection begins with colonization of host skin or mucosal surfaces and involves bacterial attachment to host cells often via components of the extracellular matrix. To persist, the organism produces molecules that decrease the effectiveness of complement-mediated and antibody-mediated opsonophagocytosis and block effectors of host immune cell killing, such as reactive oxygen species and antimicrobial peptides. Ultimately, the organism expresses specific factors that damage host cells and degrade components of the extracellular matrix, contributing to persistence and facilitating spread within normally sterile sites of the host.

## EPITHELIAL ATTACHMENT AND INVASION

*S. aureus* initiates adherence by binding to components of the extracellular matrix of the host. This adherence is mediated by protein adhesins known as MSCRAMMs

(*m*icrobial *s*urface *c*omponents *r*ecognizing *a*dhesive *m*atrix *m*olecules), which are typically covalently anchored to the cell wall peptidoglycan through the action of sortase enzymes that recognize an LP(X)TG motif in the C-terminal region of the protein [48]. *S. aureus* MSCRAMMs can promote binding to fibronectin, fibrinogen, and collagen. Most strains express two related fibronectin-binding proteins, FnBPA and FnBPB, which mediate bacterial attachment to immobilized fibronectin in vitro and contribute to *S. aureus* binding to plasma clots and foreign bodies. *S. aureus* also expresses the fibrinogen-binding proteins, or "clumping factors," ClfA and ClfB [61,62]. Each Clf protein recognizes a different part of the fibrinogen model and could synergize to allow *S. aureus* to attach more firmly to vascular thrombi under flow stress within the bloodstream. A fibronectin bridge from surface-anchored *S. aureus* ClfA to integrins in the epithelial cell surface promotes intracellular invasion by the pathogen [63]. In rat endocarditis studies, ClfA mutant *S. aureus* have reduced virulence [64]. Finally, the collagen-binding MSCRAMM Cna allows *S. aureus* to adhere to collagenous tissues such as cartilage [65]. In a murine septic arthritis model, a Cna-null mutant strain of *S. aureus* was significantly attenuated for virulence [66]. The *ica*ADBC-encoded polysaccharide intercellular adhesin (PIA) and polymeric *N*-acetylglucosamine contribute to *S. aureus* biofilm development [67]; these genes and resultant phenotype shared by *S. epidermidis* are discussed in more detail subsequently.

## INNATE IMMUNE RESISTANCE

The propensity of *S. aureus* to produce systemic infections, even in otherwise healthy infants, children, and adults, reflects the capacity of this pathogen to resist host innate immune clearance mechanisms that normally function to prevent microbial dissemination beyond epithelial surfaces. The multiple mechanisms used by this preeminent disease agent are summarized schematically in Figure 14–2.

Cationic antimicrobial peptides, such as cathelicidins and defensins produced by epithelial cells and phagocytes, are an important first line of defense against invasive bacterial infection. By incorporating positively charged residues into its cell wall lipoteichoic and teichoic acid, *S. aureus* increases electrostatic repulsion of these defense peptides. D-alanylation of teichoic acids mediated by the *dlt* operon is present in both pathogens, promoting resistance to antimicrobial peptides and neutrophil killing [68,69].

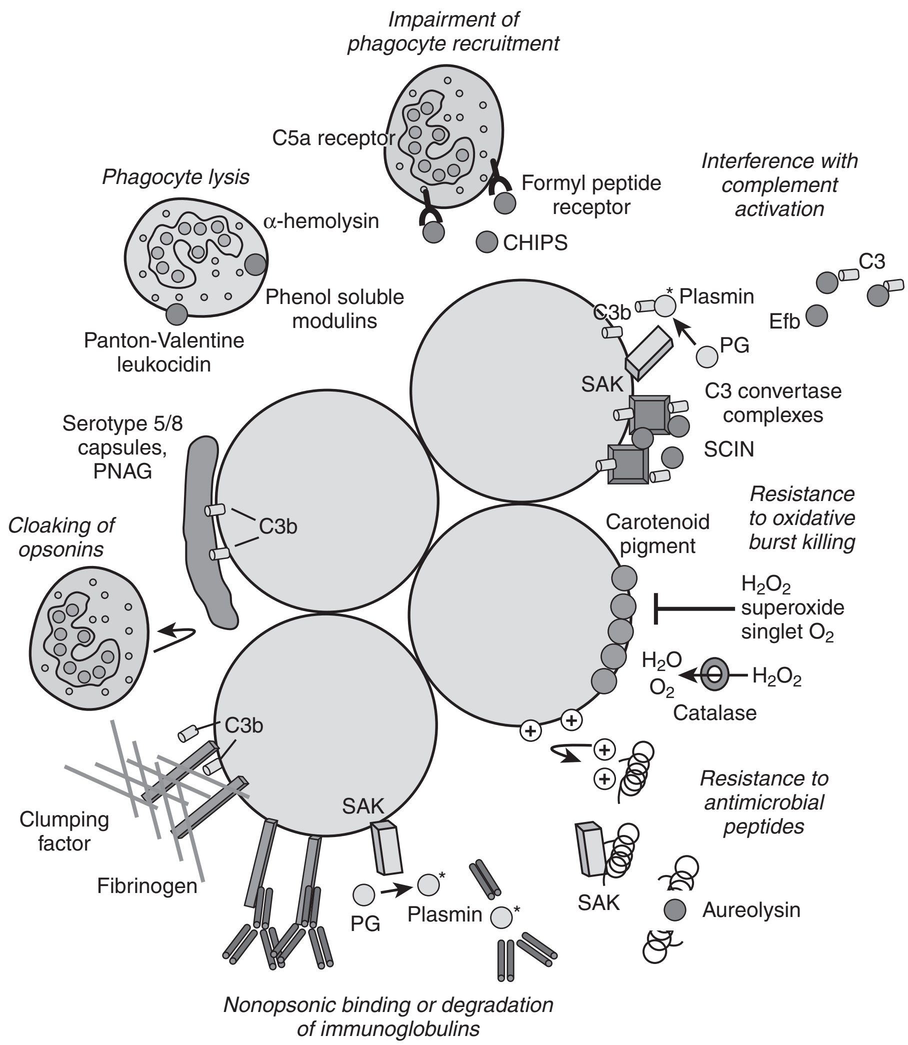

**FIGURE 14–2** ***Staphylococcus aureus*** **possesses multiple virulence mechanisms to resist clearance by host phagocytic cells.** Phagocyte recruitment is restricted by "chemotaxis inhibitory protein of staphylococci" (CHIPS) binding to chemokine receptors. Complement activation is blocked by protein Efb binding of soluble C3 and inhibition of the classical/lectin and alternative C3 convertases by staphylococcal complement inhibitor (SCIN). Carotenoid pigment provides an antioxidant shield, whereas catalase detoxifies hydrogen peroxide ($H_2O_2$). Resistance to cationic antimicrobial peptides is afforded by positive charge modifications of the cell wall, aureolysin-mediated proteolysis, and binding and inactivation by staphylokinase (SAK). Protein A binds Fc domains of immunoglobulins in a nonopsonic manner, whereas fibrinogen-binding clumping factor and the surface polysaccharide capsule and polymeric *N*-acetylglucosamine (PNAG) cloak surface-bound opsonins from phagocyte recognition. The heptameric pore-forming toxins α-hemolysin and Panton-Valentine leukocidin and phenol-soluble modulins target leukocyte membranes. The plasminogen (PG) binding protein (SAK) activates the zymogen to the active protease plasmin, which can degrade complement opsonin C3b and the immunoglobulin Fc domain.

Additionally, positively charged lysyl-phosphatidylglycerol modifications of teichoic acids are encoded in the functions the *S. aureus mpr*F or *lys*C genes and contribute to human antimicrobial peptide resistance [70,71]. *S. aureus* mutants defective in Dlt or MprF show reduced virulence in small animal infection models [69,72]. The secreted proteases V8 and aureolysin of *S. aureus* function to degrade antimicrobial peptides, which could contribute further to *S. aureus* resistance to this important branch of the innate defense system [73,74].

Many *S. aureus* strains produce the "chemotaxis inhibitory protein of staphylococci" that binds with high avidity to the leukocyte receptors for C5a and *N*-formyl peptides, blocking functional engagement of the respective chemoattractants and delaying neutrophil recruitment to the site of infection [75]. *S. aureus* also expresses the extracellular adherence protein that binds and inhibits intracellular adhesion molecule 1, the endothelial receptor required to initiate leukocyte adhesion and diapedesis [76].

*S. aureus* expresses multiple factors to interfere with host complement-mediated clearance [77]. Cleavage of C3 to opsonically active C3b is accomplished after assembly of C3 convertase complex C4bC2a (classic/lectin pathways) or C3bBb (alternative pathway) on the bacterial surface. The secreted approximately 10 kDa *S. aureus* protein known as staphylococcal complement inhibitor binds and stabilizes both convertases on the bacterial surface, preventing generation of additional convertases, impairing their enzymatic activities, and effectively inhibiting all three complement pathways [78]. The surface-anchored *S. aureus* fibrinogen-binding protein ClfA recruits fibrinogen to the bacterial surface in a fashion that impairs complement deposition [79,80]. The secreted *S. aureus* fibrinogen-binding protein Efb-C can bind free C3, altering the solution conformation of this crucial complement component such that it is unable to participate in its downstream opsonization functions [81]. Finally, another mechanism of interference with complement opsonization derives from bacterial coaptation of host proteolytic activities. The *S. aureus* surface receptor staphylokinase binds plasminogen from host serum and converts zymogen to the active protease, plasmin. Surface bound plasmin can cleave human C3b and C3bi from the bacterial cell wall and impair neutrophil phagocytosis [82].

*S. aureus* is able to inhibit effector function of immunoglobulin when the pathogen binds its Fc region, effectively decorating the bacterial surface with the host molecule in a "backwards," nonopsonic orientation [83]. This Fc-binding activity is classically associated with protein A of *S. aureus*, which serves to block Fc receptor–mediated phagocytosis and contributes to animal virulence [84]. In addition, most *S. aureus* clinical isolates express surface capsules composed of serotype 5 or 8 polysaccharide [49]. The presence of *S. aureus* capsule is associated with reduced opsonophagocytic uptake of the pathogen by neutrophils and increased virulence in a mouse bacteremia model [85,86]. Analogous functions can be ascribed to an additional *S. aureus* surface polysaccharide, polymeric *N*-acetylglucosamine [87]. Neither of the *S. aureus* exopolysaccharides directly inhibits deposition of complement factors on the bacterial surface; rather, they seem to serve as a superficial "cloak" that restricts access of phagocytes to the opsonins [83].

Catalase production is a diagnostic tool to distinguish staphylococci from streptococci in the clinical laboratory, and the ability of staphylococcal catalase to detoxify hydrogen peroxide generated during oxidative burst may promote phagocyte resistance and virulence [88]. The golden pigment for which *S. aureus* is named is a carotenoid molecule with potent antioxidant properties that is necessary and sufficient to promote bacterial neutrophil resistance and virulence in subcutaneous infection models [89,90]. *S. aureus* also resists oxidative stress through superoxide dismutases, as confirmed by diminished in vivo survival of mutants lacking these enzymes [91].

## SECRETED TOXINS

Numerous toxins secreted by *S. aureus* possess cytolytic activity against host cells and can facilitate tissue spread; promote inflammatory responses; and, especially when the target is a phagocytic cell, promote bacterial innate immune evasion. Perhaps the best-studied toxin is *S. aureus* α-toxin (also referred to as α-hemolysin), which forms heptamers in the membranes of various cell types, creating large pores [92,93]. Pore formation induced by *S. aureus* α-toxin is associated with release of nitric oxide from endothelial cells and stimulation of apoptosis in lymphocytes [94,95]. *S. aureus* production of α-toxin may also promote escape from the phagolysosome after macrophage engulfment [96]. MRSA production of α-toxin is essential for virulence of the pathogen in the mouse model of pneumonia [97]. The level of α-toxin expression by differing *S. aureus* strains directly correlates with their virulence. Immunization with an inactivated form of α-toxin, which cannot form pores, generates antigen-specific IgG responses and provides protection against MRSA pneumonia [98].

*S. aureus* also produces an additional family of two-subunit heteroheptameric toxins capable of oligomerizing in the membrane of target leukocytes to produce pores and promote hypo-osmotic cell lysis. These include γ-hemolysin and the bacteriophage encoded Panton-Valentine leukocidin (PVL) [99]. PVL has gained notoriety because of its strong epidemiologic association with severe cases of CA-MRSA infections [100]. The true contribution of the PVL toxin to *S. aureus* virulence is uncertain. Phage transduction of PVL into a previously naïve *S. aureus* background was reported to increase virulence in a murine necrotizing pneumonia model [101], but an inadvertent mutation in the *agr* regulatory locus of the test strain probably led to spurious interpretations of the PVL linkage to disease pathogenesis [102]. A more direct test of isogenic deletion of PVL in the epidemic USA300 and USA400 clones associated with severe CA-MRSA infections had no effect on neutrophil lysis or virulence in murine skin abscess and systemic infection models [103], but did contribute to proinflammatory cytokine release and muscle necrosis at higher inocula and in certain mouse genetic backgrounds [104]. PVL is much more active against human neutrophils than murine neutrophils, explaining some of the limitations of this animal species as a model for analysis of the virulence functions of the cytotoxin.

Other toxins secreted by *S. aureus* include β-hemolysin, a sphingomyelinase enzyme [105]. Through targeted mutagenesis, β-hemolysin more recently was found to contribute to *S. aureus*–induced lung injury, neutrophilic inflammation, and vascular leakage of serum proteins into the alveolar spaces, in part mediated by the ability of the toxin to promote ectodomain shedding of syndecan-1, a major proteoglycan coating lung epithelial cells [106]. Phenol-soluble modulins are a novel family of small, amphipathic, α-helical cytolytic peptides with in vitro and in vivo leukocidal and proinflammatory activities [107]. Phenol-soluble modulins are produced at high levels by CA-MRSA compared with HA-MRSA and contribute to virulence in necrotizing skin and bacteremia mouse models of infection [108].

*S. aureus* elaborates numerous toxins with superantigenic capacity, able to promote aberrant interaction between MHC class II on the surface of antigen-presenting cells (e.g., macrophages) with the β-chain of the T-cell receptor, leading to polyclonal T-cell activation and potentially staphylococcal TSS [109]. Twenty distinct *S. aureus* superantigens are known, prominently including TSS toxin-1 and staphylococcal enterotoxins A through E and G through J. The genes encoding the *S. aureus* superantigens are present on accessory genetic elements such as prophages, transposons, plasmids, and chromosomal pathogenicity islands. The contribution of the superantigens to the severe disease manifestations of *S. aureus* are well shown, but the potential evolutionary advantage of superantigen production to the pathogen is unclear. One possible advantage of T-cell activation at the site of infection might be dysregulated cytokine expression patterns that suppress effective local inflammatory responses [109].

Certain strains of *S. aureus* express the exfoliative (epidermolytic) toxins ETA, ETB, ETC, or ETD. These toxins have been identified as glutamate-specific serine proteases that specifically and efficiently cleave a single peptide bond in the extracellular region of human and mouse desmoglein 1, a desmosomal intercellular adhesion molecule, leading to the exfoliative phenotype of scalded skin syndrome and bullous impetigo [110,111].

## QUORUM SENSING AND REGULATION OF VIRULENCE FACTOR EXPRESSION

*S. aureus* seems to impose tight regulation on the differential expression of specific sets of virulence determinants at different stages of growth or the pathogenic process. Cell wall–associated adhesive factors that facilitate the initial stages of infection are selectively produced during the exponential phase of in vitro growth [112]. Conversely, almost all *S. aureus* extracellular proteins and secreted toxins presumed to play a greater role in evasion of the immune system and tissue spread are synthesized predominantly in the postexponential phase of growth [112]. These processes are under the cell density (quorum sensing)–dependent control of the accessory gene regulator (*agr*) locus [113,114]. Similar to other bacterial quorum sensing systems, *agr* encodes an autoactivating peptide (AIP) that is the inducing ligand for a signal receptor (AgrC), the *agr* signal receptor. The unique effector of global gene regulation in the *agr* system is the regulatory RNA molecule, RNAIII [114]. *agr* mutants show decreased virulence in murine infection models [115].

## VIRULENCE MECHANISMS OF COAGULASE-NEGATIVE STAPHYLOCOCCI

Until more recently, the pathogenic potential of CoNS received little attention. With the emergence of these organisms as prominent pathogens in neonates and hospitalized patients with intravascular devices, investigation has intensified in an effort to identify important virulence factors and to inform new approaches to treatment and prevention [116]. Two main reasons for the increasing rate of CoNS infections are spreading antibiotic resistance among CoNS and the ever-increasing development and use of medical devices [117]. Attention has centered primarily on *S. epidermidis*, the species most commonly associated with clinical disease, usually in association with central intravenous catheters. Other species that have been examined, although to a lesser extent, include *S. saprophyticus*, *S. lugdunensis*, and *S. schleiferi*.

When CoNS infections are initiated on intravascular catheters and other prosthetic devices, the ability of the bacterium to adhere to the hydrophobic surface of the foreign body is a first critical step in the pathogenic process (Fig. 14–3). CoNS are able to colonize virtually any plastic surface [118]. In addition, plastic objects in the human body soon become coated with host extracellular matrix proteins [119], such that CoNS can colonize the devices either by directly attaching to the plastic or by binding to the host extracellular matrix, and both processes are likely to play a role in the initial establishment of infection. Overall surface hydrophobicity varies among CoNS strains, and increased hydrophobicity can be correlated to better plastic binding [120]; however, no linkage between surface hydrophobicity and clinical infectivity has been established [117].

Transposon mutagenesis identified AltE, a putative CoNS autolysin protein, as promoting adherence to plastic surfaces [121]; in a rat model of catheter-associated infection, *S. epidermidis* AltE mutant shows diminished pathogenicity [122]. Two large surface proteins present in some *S. epidermidis* strains—SSP-1 and SSP-2, one likely a degradation product of the other—are present in fibrillar structures on the bacterial surface and promote binding to polystyrene [123].

Following in the pattern of *S. aureus*, extracellular matrix binding surface components or MSCRAMMs are beginning to be well characterized in CoNS. The fibrinogen-binding protein Fbe (also known as SdrG) of *S. epidermidis* resembles *S. aureus* clumping factor with the presence of

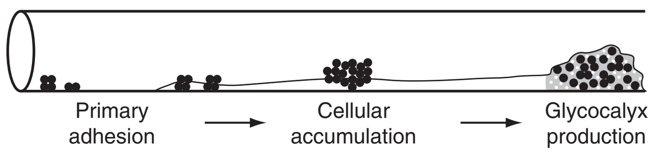

**FIGURE 14–3** Schematic model of phases involved in *Staphylococcus epidermidis* biofilm formation.

multiple serine/aspartic repeat domains and a capacity to bind to the β-chain of the host matrix protein [124–126]. *S. epidermidis* cell wall teichoic acid enhances overall adherence to fibronectin, perhaps serving as a bridging molecule between bacterial MSCRAMMs and fibronectin-coated surfaces [127]. Phage-display technology was used to identify *S. epidermidis* protein, EmbP, capable of mediating binding to fibronectin, whereas *S. epidermidis* lipase enzyme, GehD, seems to promote collagen attachment [128]. Finally, the above-mentioned AltE also contains a domain with vitronectin-binding capacity that may contribute to its virulence phenotype in the rat model [121].

After initial attachment to a biomaterial, organisms multiply and form complex multilayered aggregates that involve intercellular adhesion and are referred to as biofilms (Fig. 14–4; see also Fig. 14–3). Historically, isolates of CoNS were often described as elaborating “slime” and “slime-associated antigen,” terms that we now realize refer to biofilms and the presence of abundant quantities of a specific polysaccharide molecule. Significant degrees of slime production were reported in more than 80% of CoNS isolates from infants with invasive disease [129,130]. The main virulence factor responsible for the formation of these cellular aggregates in certain *S. epidermidis* strains is now recognized to be a secreted exopolysaccharide, PIA [131,132]. PIA is an unbranched β-1, 6-linked *N*-acetylglucosaminic acid polymer, produced by the enzymes of the four-gene *ica* operon [133]. An *ica* knockout mutant shows reduced virulence in a rat model of catheter infection [122], and *S. epidermidis* strains isolated from patients with foreign infections were more likely to possess the *ica* genes and form robust biofilms in vitro than strains from asymptomatic individuals [134]. Expression of PIA is subject to on-off phase-switching that may be attributable to reversible insertion and excision of mobile genetic element (IS256) in the *ica* operon [135]. A 140-kDa CoNS extracellular protein known as accumulation-associated protein apparently cooperates with PIA in promoting biofilm growth [136].

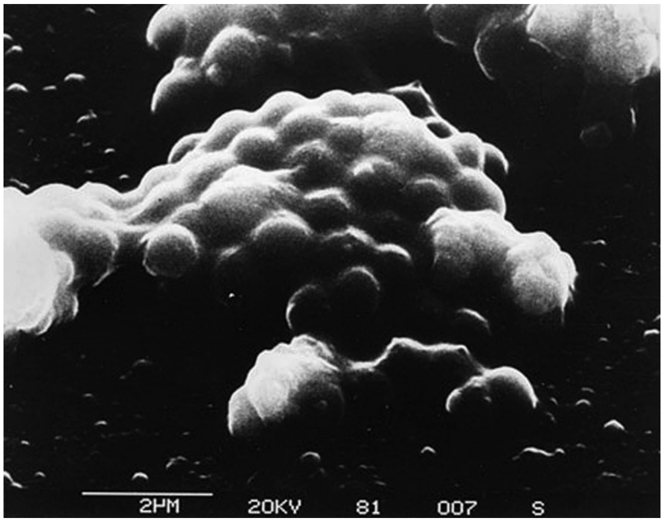

**FIGURE 14–4 Scanning electron micrograph showing the presence of a *Staphylococcus epidermidis* biofilm on an explanted intravascular catheter.** Biofilm is characterized by multilayered cell clusters embedded in an extracellular polysaccharide. *(From von Eiff C, Peters G, Heilmann C. Pathogenesis of infections due to coagulase-negative staphylococci. Lancet Infect Dis 2:677-685, 2002.)*

CoNS biofilm provides a nonspecific physical barrier to cellular and humoral defense mechanisms [132,137]. The formation of CoNS biofilms depends on the regulatory control exerted by a homologue of the *S. aureus agr* locus [138]. *S. epidermidis* organisms embedded within biofilms bind less complement C3b and IgG and are less susceptible to neutrophil killing [139]. CoNS biofilm–associated polysaccharide also is capable of inhibiting the antimicrobial action of vancomycin and teicoplanin [140]. In the clinical setting, formation of biofilms on the catheter surface has been shown to make eradication of CoNS infection more problematic [141,142].

*S. epidermidis* expresses a 27-kDa serine protease called GluSE that is expressed during biofilm formation and has been shown to degrade fibrinogen and the complement-derived chemoattractant C5, suggesting a potential role in immune evasion [143]. *S. epidermidis* also expresses a group of secreted amphiphilic peptides called phenol-soluble modulins that have neutrophil chemotactic ability and generate other proinflammatory effects including activating neutrophil oxidative burst and degranulation [144].

## ROLE OF THE HOST DEFENSES

Even under the most ideal conditions, infants in the hospital are surrounded by staphylococci. Physical barriers such as the skin and mucous membranes represent a major defense against staphylococcal disease. Bacteremic disease most often develops when organisms colonizing the skin gain access to the bloodstream through the portal created by an intravascular catheter. Other routes for entry into the bloodstream include the intestinal tract after injury to the epithelial barrier, the respiratory tract in patients receiving mechanical ventilation, and the umbilicus when the umbilical cord remains in place. Localized disease occurs when colonizing organisms are implanted into deeper tissues, often related to a break in skin or mucous membrane integrity and sometimes during placement of a foreign body.

As with other pathogenic bacteria, the presence of intact neutrophil phagocytic function is probably the most important factor involved in controlling replication and spread of staphylococci [145]. The ability of the newborn’s bone marrow to respond to infection with rapidly enhanced production and maturation of neutrophil precursors is limited compared with adults [146]. Neutrophils from newborns have relatively diminished motility toward chemoattractants compared with cells from older children and adults [147]; this is partly the result of diminished chemotactic factors such as the complement-derived C5a and the CXC chemokine interleukin (IL)-8 [148,149]. Neutrophils from young infants also exhibit decreased diapedesis across endothelium, possibly because of impaired capacity to upregulate endothelial cell expression of the CR3 receptor [150]. Beyond decreases in neutrophil number, chemotaxis, and trans-epithelial migration, the capacity for neutrophil adherence and phagocytosis is reduced in neonates, largely

owing to deficiencies in opsonins, including complement and specific antibody [145].

Phagocytic killing seems to be intact in normal newborns, but may be compromised in stressed infants, at least in part because of reduced production of reactive oxygen species [151,152]. The multifaceted antioxidant capacities of *S. aureus*, including catalase and the carotenoid pigment, likely support its prominent role as an opportunistic pathogen in stressed infants and in patients with chronic granulomatous disease, where defects in reduced nicotinamide adenine dinucleotide phosphate oxidase lead to marginal oxidative burst function. Chronic granulomatous disease may occasionally present with *S. aureus*, *Serratia*, or *Aspergillus* infection in the neonatal period [153].

Specific antibody is less important than complement in opsonization of *S. aureus* and plays a limited role in defense against neonatal staphylococcal disease [154]. In general, there is no correlation between antibody titers against *S. aureus* and the likelihood of asymptomatic carriage versus clinical disease [155,156]. Consistent with this information, an attempt to protect the newborn from staphylococcal disease by immunizing the mother near term was unsuccessful [157].

In most cases of neonatal staphylococcal disease, the role of T cells is unclear. In animal models, T cells are found to contribute to the development of abscesses during *S. aureus* infection [158]. T cells are centrally involved, however, in the immune response to several *S. aureus* toxins, including TSST-1, the staphylococcal enterotoxins, and the staphylococcal exfoliative toxins (ETA, ETB, ETC, and ETD), and in associated pathogenesis. The consequence of this dysregulated T-cell overactivation is proliferation of a large proportion of T cells and release of numerous cytokines, including tumor necrosis factor (TNF)-α, IL-1, and interferon-γ [159]. These molecules are major contributors to the systemic manifestations of staphylococcal scalded skin syndrome (SSSS), TSS, and food poisoning.

## PATHOLOGY

The most characteristic pathologic lesion associated with *S. aureus* infection is a local abscess, consisting of necrotic tissue, fibrin, and numerous live and dead neutrophils. Similarly, CoNS infection is characterized by infiltration of neutrophils, usually with moderate necrosis. Other pathologic findings are described next in the sections on clinical manifestations.

## CLINICAL MANIFESTATIONS

Staphylococci are capable of producing a wide variety of clinical syndromes in the newborn infant, including syndromes with high mortality rates, as was reviewed almost 50 years ago [160]. The clinical manifestations of staphylococcal infection are most prominently a function of two factors: the gestational age of the infant, with extremely low birth weight infants at highest risk of infection and subsequent complications, and the strain of *Staphylococcus* causing the infection, with CoNS generally causing more mild infection compared with *S. aureus*, particularly relevant to more recent CA-MRSA. As noted earlier, staphylococci are armed with an impressive array of virulence factors. They may merely colonize skin or respiratory or gastrointestinal tract mucosa without apparent harm to the host or cause invasive, lethal disease. CoNS are most often benign colonizers of skin and gastrointestinal tract in newborns, causing frequent but relatively mild infections in hospitalized premature infants. In contrast, coagulase-positive strains (*S. aureus*) are more commonly associated with clinically aggressive, invasive infections. The subsequent sections provide a general overview of clinical manifestations and organ-specific manifestations.

## BACTEREMIA AND SEPSIS

The most common manifestations of invasive staphylococcal infection are bacteremia and sepsis. Studies describing symptomatic community-acquired and hospital-acquired bacteremia in neonates provide an overall framework in which CoNS and *S. aureus* infection can be defined and include early-onset sepsis and late-onset sepsis syndromes [6,25,161–175].

Early-onset sepsis is most often related to acute infectious complications of late pregnancy and delivery or colonization of the infant at birth and subsequent development of clinical symptoms within the first 48 to 72 hours of life [176]. The signs and symptoms associated with staphylococcal septicemia usually are nonspecific and include disturbances of temperature regulation, respiration, circulation, gastrointestinal function, and central nervous system activity. Hypothermia is more common than fever and often is observed as the initial sign. Respiratory distress frequently manifests as episodes of apnea and bradycardia, particularly in infants who weigh less than 1500 g. Other abnormalities related to respiration include tachypnea, retractions, and cyanosis. In 20% to 30% of infants, gastrointestinal abnormalities develop, including poor feeding, regurgitation, abdominal distention, diarrhea, and bloody stools. Evidence of poor perfusion includes mottling and poor capillary refill. In some infants, lethargy, irritability, or poor suck may also be noted.

The incidence of early-onset sepsis caused by *S. aureus* seems to reflect the characteristics of circulating strains and varies by year and region of the world (see "Epidemiology and Transmission"). Clinical descriptions of staphylococcal sepsis include a positive blood culture, usually in the context of nonspecific clinical signs and symptoms that may include apnea, bradycardia, irritability, poor feeding, abdominal distention, lethargy, hypotonia, hypothermia or hyperthermia, hypotension with poor tissue perfusion, cyanosis, and increased oxygen requirement with respiratory distress. In an ongoing 75-year collection of data from Yale–New Haven Hospital [7], *S. aureus* represented the etiology of early-onset sepsis from 28% (1928-1932) to 3% (1979-1988), with a current rate (1989-2003) of 7%. Mortality from all causes of early-onset sepsis declined from about 90% with the earliest data set to approximately 5% of all newborn infants in 1989-2003.

A report from Finland documented *S. aureus* as an etiology of sepsis from 1976-1980 in 22% of all infants with positive blood cultures [177], with an overall mortality rate

of 31%, although for infants with birth weight 1500 g or less, the mortality rate was 44%. Published data from centers in Australia and New Zealand from 1992-1999 documented *S. aureus* rates that varied considerably by year and by institution, with differences in rates even noted within different hospitals in the same city [163], resulting in an overall rate of 19 cases out of 244,718 births (0.008%). In this report, MRSA accounted for only 8% of cases from 1992-1994, but 34% of cases from 1995-1998. Of 26 cases of *S. aureus* sepsis documented in 1999, none were caused by MRSA. The overall mortality rate from MRSA was 25% compared with 10% for MSSA.

Early-onset sepsis caused by CoNS is reported extremely infrequently, likely because of the noninvasive nature of most strains. These reports may reflect true infection, particularly in very low birth weight infants [167,178], although the extent of symptoms attributable to infection in these infants is difficult to assess. Otherwise, particularly for term infants, a positive culture of blood for CoNS may represent a contaminant, unrelated to the underlying illness.

When considering late-onset neonatal sepsis syndrome, occurring after the 5th day of life in hospitalized infants, *S. aureus* and CoNS are well-documented pathogens. In the NICHD Neonatal Research Network, *S. aureus* was the second most common pathogen to cause late-onset sepsis in very low birth weight (401 to 1500 g) infants [6]. CA-MRSA produces particularly devastating infection, with seven of eight infants hospitalized in the NICU of Texas Children's Hospital in Houston presenting in septic shock; the case-fatality ratio was 38% in this series, despite appropriate support and antimicrobial therapy [179]. In a maternity hospital in Houston during the same period, mortality attributable to the invasive *S. aureus* infection was 6%, with late sequelae attributable to infection of 12% [179]. In this report, only 3 of 39 *S. aureus* infections were caused by MRSA; all 3 infants recovered without sequelae.

In a retrospective review of 12 neonates with bacteremia caused by MSSA compared with 11 neonates infected by CA-MRSA, collected during 1993-2003 in Tel Aviv, Israel, mortality rates were virtually identical, 25% versus 27% [172]. In a larger series of 90 infants from Taiwan with bacteremia caused by MRSA, 75% of infants were premature, 54% of infections were believed to be catheter-related, 21% were associated with skin and soft tissue infections, 17% were associated with pneumonia, 8% were associated with bone and joint infection, 3% were associated with meningitis, and 3% were associated with peritonitis [180]. This rate of metastatic infection attributed to MRSA seems greater than that noted with MSSA and is clearly greater than rates seen with CoNS bacteremia. Of infants with resolved MRSA infection, 10% had at least one recurrence. At Duke University Medical Center, mortality and neurodevelopmental outcomes in infants with bacteremia caused by MSSA (median age 26.5 days) were compared with MRSA (median age 26 days) [181]. Although the duration of staphylococcal bacteremia was shorter in neonates with MSSA (1 day versus 4.5 days), the mortality and neurodevelopmental outcomes were statistically similar to infants infected with MRSA.

The largest burden of disease in late-onset sepsis caused by staphylococci is catheter-related CoNS bacteremia in premature infants. In the NICU, CoNS cause 40% to 60% of all documented bacteremia [6,162,182,183]. Rates of catheter-associated bacteremia have been tracked by the U.S. Centers for Disease Control and Prevention [184] and other collaborative groups, including the Pediatric Prevention Network [161] and the Vermont Oxford National Evidence-Based Quality Improvement Collaborative for Neonatology [185]. Clinical manifestations of infection are frequently related to the gestational and chronologic age of the newborn, but are most often nonspecific. In a retrospective review of invasive staphylococcal infections in a maternity hospital in Houston, Texas, during 2000-2002, bacteremia was present in 94% of 108 infants with invasive CoNS infection, resulting in a wide range of nonspecific symptoms, including apnea and bradycardia in 52%, an increased oxygen requirement in 90%, lethargy in 31%, abdominal distention in 30%, increased blood pressure support requirement in 22%, and temperature instability in 18% [178]. Similar findings were published by investigators in the Neonatal Research Network, sponsored by the NICHD [186], highlighting the burden of disease in very low birth weight infants.

CoNS infections have often been associated with many risk factors (see "Epidemiology and Transmission"), but the ultimate outcome of infants infected with CoNS may more closely follow their comorbidities than be linked to bacterial pathogenicity. In a review of data collected by the Pediatrix Medical Group, Benjamin and colleagues [165] noted that the survival of low birth weight infants ($\leq$1250 g) after a positive blood culture for CoNS was virtually identical (8%) to survival of infants evaluated for sepsis yielding sterile blood cultures, in contrast to much higher rates of mortality with gram-negative organisms or *Candida*. Similar findings suggesting lack of attributable mortality to CoNS bacteremia documented that for infants who ultimately died of any cause, death occurred more than 7 days after the positive blood culture for CoNS in 75% of infants [6]. These findings were also confirmed in very low birth weight infants in Israel, reporting on 3462 episodes of late-onset sepsis, documenting a mortality within 72 hours of CoNS bacteremia of only 1.8% [187]. Other authors have suggested that persisting positive blood cultures for CoNS, despite appropriate antibiotic coverage, are associated with an increase in overall complications, with a mortality of 7% [164].

Treatment of catheter-associated CoNS infections is controversial. Karlowicz and colleagues [188] prospectively evaluated treatment with vancomycin versus catheter removal. In neonates treated with vancomycin who experienced clearing of bacteremia within 1 to 2 days, success without catheter removal occurred in 79%, whereas in neonates with persisting bacteremia of 3 to 4 days, the success rate declined to 44%, and in neonates with bacteremia persisting beyond 4 days, none were successfully treated with medical therapy alone, a finding similar to that reported by Benjamin and associates [189] in a retrospective review, in which the rate of metastatic infection increased significantly after four or more positive cultures. Other authors have attempted to limit

the empirical use of vancomycin in the NICU by comparing outcomes using vancomycin-containing empirical regimens during one period of study with cloxacillin-containing regimens during another period. When all-cause mortality was assessed at 14 days after positive blood culture, 0 of 45 infants receiving vancomycin versus 4 of 37 infants not receiving vancomycin had died. When examined on a individual case basis, only one of the deaths was possibly attributed to CoNS sepsis [190].

## TOXIC SHOCK SYNDROMES

In addition to clinical manifestations related to bacteremia, toxin-mediated clinical disease may occur, including SSSS (see later), TSS [191], and neonatal TSS-like exanthematous disease [192]. TSS is caused by pyrogenic toxin superantigens produced by *S. aureus*. These superantigens include TSST-1 and several enterotoxins, most commonly staphylococcal enterotoxin serotype B or C [193,194]. TSS has been described in a 4-day-old term infant boy, with poor feeding and vomiting at 3 days of age, followed by hypotension, respiratory distress, and multiorgan failure on day 4 of life. Generalized erythema developed at 6 days of age. This infant was colonized on the umbilicus with a methicillin-susceptible strain that produced staphylococcal enterotoxins C, G and I [191].

A similar disease has been described in Japan, caused by MRSA, producing erythema in association with thrombocytopenia, elevated C-reactive protein, or fever [195]; this presentation has been termed neonatal TSS-like exanthematous disease (Fig. 14–5) [196]. Since the time of the first description, surveys in Japan have shown that 70% of Japanese hospitals have reported a similar illness in neonates [197]. The causative strains all carried the TSST-1 gene and the staphylococcal enterotoxin C gene [192]. The pathophysiology of neonatal TSS-like exanthematous disease begins with colonization with MRSA, a common occurrence among Japanese newborns. Typically, the colonizing strain of MRSA produces TSST-1 [192], and the symptoms of the disease are related to the overactivation of TSST-1–reactive T cells [196]. Neonatal TSS-like exanthematous disease does not develop in all infants who are colonized with TSST-1–producing MRSA, suggesting that protection from this illness may be mediated by the transplacental transfer of maternal antibody directed against TSST-1 [197].

**FIGURE 14–5** Typical exanthem in full-term infant with neonatal toxic shock syndrome–like exanthematous disease. *(From Takahashi N, et al. Exanthematous disease induced by toxic shock syndrome toxin 1 in the early neonatal period. Lancet 351:1614-1619, 1998.)*

## ENDOCARDITIS

Although infective endocarditis in neonates is rare, autopsy studies from the 1970s revealed unsuspected endocarditis in 0.2% to 3% of neonates who were examined post-mortem [198,199]. Historically, *S. aureus* has been the predominant bacterial pathogen among neonates with endocarditis [200], but more recent reports indicate that CoNS is now most common [201–204]. Premature infants with prolonged central catheter bacteremia and infants with congenital heart disease are most likely to develop *S. aureus* endocarditis in association with bacteremia [202,204–208]. Endocarditis has also been described in infants infected by CA-MRSA [209].

The signs and symptoms of infective endocarditis in neonates often are nonspecific and similar to signs and symptoms of other conditions such as sepsis or congenital heart disease, including poor feeding, tachycardia, and respiratory distress [200]. Clinical features in general may be unable to distinguish bacteremia with endocarditis from infants with bacteremia without endocarditis [204]. Murmurs can be appreciated in 75% of neonates with endocarditis, with hepatosplenomegaly present in 50%, skin abscesses in 44%, arthritis in 12%, and petechiae in 12%. Blood cultures and echocardiography are the most important diagnostic tests, although urine cultures may be positive in 38% [202,207]. The yield of a single blood culture has been reported to be 77% to 97%. When three blood cultures are obtained, the yield approaches 100% [207].

All neonates with *S. aureus* bacteremia should be evaluated by echocardiogram. The thin chest wall of the neonate makes echocardiography a highly sensitive tool for diagnosis of endocarditis in this age group. Limitations of this technique include the inability to detect lesions less than 2 mm in diameter and to differentiate between vegetations and other masses such as thrombi [202]. In all age groups of children, 12% of children with bacteremia with *S. aureus* may have clear evidence of endocarditis; children with underlying congenital heart disease and *S. aureus* bacteremia have a much greater risk of endocarditis compared with children with no cardiac malformations (53% versus 3%) [205]. Mortality in children with *S. aureus* bacteremia and endocarditis has been reported to be 40% [205].

In the Australasian Study Group for Neonatal Infections, bacteremia caused by CoNS in 1281 infants during 1991-2000 was associated with endocarditis in 3 (0.2%); in infants with bacteremia caused by *S. aureus*, endocarditis occurred in 3 of 223 (1.3%) infected with MSSA strains and in 1 of 65 (2%) infected with CA-MRSA strains. Historically, the prognosis for neonates with endocarditis has been grave. Numerous series published in recent years report disease-specific survival rates ranging from 40% to 70% [202,204,207]. Survival of neonates with infective endocarditis is likely to be improved with early diagnosis and aggressive management [200].

## PUSTULOSIS, CUTANEOUS ABSCESS, AND CELLULITIS

For infants presenting to Texas Children's Hospital in Houston, skin infection was the most common manifestation of staphylococcal disease (88%) in term or late preterm infants (≥36 weeks of gestation). Of infants with skin infection, about two thirds presented with cellulitis or abscess, whereas one third presented with pustulosis, a localized, nonsystemic, invasive cutaneous form of infection [210]. Two thirds of all *S. aureus* infections were caused by CA-MRSA, with CA-MRSA and MSSA manifesting with skin or invasive infection in roughly equal percentages; the proportion of infections caused by CA-MRSA increased over the period of observation from 2001-2006 [210,211]. A similar experience was reported from Chicago, in which 11 infants less than 1 month of age were culture-positive for CA-MRSA, with cutaneous lesions consisting of pustules and vesicles, most commonly present in the diaper area. Resolution of cutaneous infection occurred with the use of mupirocin ointment. No infant required surgical drainage, and no infant developed systemic manifestations of disease or required hospitalization with intravenous antibiotic therapy [212]. Similar clusters of skin-only pustules and vesicles have been reported from other centers [213].

Evaluation of newborn infants discharged from the hospital, but readmitted within 30 days of age, provided a different profile of clinical disease caused by staphylococci [210]. Infants infected with MRSA presented at 7 to 12 days of age, in contrast to infants infected with MSSA, whose presentations occurred evenly spaced over the 1st month of life. Most of these infants (87% for MRSA and 86% for MSSA) presented with skin and soft tissue infection. Cellulitis with or without abscess was responsible for about two thirds of hospitalizations. Pustulosis, primarily involving skin covered by a diaper, was the most prominent sign in approximately one third of infections. Invasive disease occurred in about 10% of infants, including bacteremia, urinary tract infection, osteomyelitis, myositis, and empyema. A study of the clinical characteristics of neonates hospitalized in a level III (40-bed) NICU and cultured weekly from the nose and inguinal areas to assess ongoing colonization status showed that of 152 infants known to be colonized over the study period 2002-2004, 6 (3.9%) developed MRSA sepsis, 3 (2%) developed conjunctivitis, 2 (1.3%) developed chest tube site wound infections, and 2 (1.3%) developed cellulitis [214].

## ADENITIS AND PAROTITIS

*S. aureus* cervical adenitis can be another manifestation of nursery colonization in newborns. At least two outbreaks of cervical adenitis resulting from nurseries were reported in 1972. One outbreak involving 25 infants had an attack rate of 1.9%, and another involving 9 infants had an attack rate of 5.6% [215,216]. As with other manifestations of nursery-associated *S. aureus* disease, illness usually appears after discharge from the hospital. The mean incubation periods in the two outbreaks in England were 86 days and 72 days. Because of the delay in onset of disease, confirmation of a nursery as the source of the infection may be difficult and necessitates careful epidemiologic investigation. Neonatal suppurative parotitis is an uncommon infection among newborns, occurring with an incidence of 13.8 per 10,000 admissions [217]. Premature neonates and boys seem to be at highest risk for suppurative parotitis, which is most frequently caused by *S. aureus* [218,219]. Diagnosis of suppurative parotitis relies on the clinical findings of parotid swelling and purulent exudate from Stensen duct on compression of the parotid gland [220].

## BREAST INFECTION

A series of 39 neonatal breast abscesses caused by *S. aureus* were reported by Rudoy and Nelson [221] from Dallas, Texas, in 1975. These infants developed infection most commonly during the 2nd week of life, when neonatal breast tissue is still enlarged in response to transplacental estrogens. The infection is clinically easy to detect, with acute onset of swelling, erythema, and tenderness of the affected breast, with progression of the infection over several hours, occasionally spreading to surrounding tissues (Fig. 14–6). Spontaneous drainage of purulent material from the infant's breast may or may not occur. Culture and Gram stain of purulent discharge is diagnostic. Management includes systemic antistaphylococcal antimicrobials and careful surgical drainage of abscessed tissue within the breast, particularly in female infants. In the report from Dallas, one third of infant girls followed into early adolescence were documented to have decreased breast size as a complication of the infection [221].

In other series of cases in which follow-up histories were obtained, a decrease in breast size was noted in two of six individuals who were examined at ages 8 and 15 years [221,222]. A series of three female neonates with necrotizing fasciitis as a complication of breast infection and abscess was collected from the Hôpital Necker in Paris over a 30-year period, all caused by MSSA, with no infant having a concurrently positive blood culture. All infants survived after extensive surgery and prolonged antibiotic therapy. In one of three cases followed through puberty, breast development did not occur on the affected side [223]. Antimicrobial therapy should be provided intravenously until a clear, substantial response can be documented. In locations with a high prevalence of CA-MRSA, therapy should include clindamycin or vancomycin.

## FUNISITIS, OMPHALITIS, AND NECROTIZING FASCIITIS

Funisitis, mild inflammation of the umbilical stump with minimal drainage and minimal erythema in the surrounding tissue, is a local, noninvasive entity. Infections of the umbilical stump may become invasive, however, and occur in a full spectrum of clinical presentations from funisitis to massive abdominal wall inflammation with erythema and indurative edema associated with necrotizing fasciitis. In an attempt to define the stages of the spectrum of infection, some experts have separated the infection into

**FIGURE 14–6** **A** and **B**, Left breast abscess in a 12-day-old infant. Abscess extends toward the right side of chest and up over the arm. The infant responded well to incision and drainage and antibiotic treatment.

distinct categories: category 1, funisitis and umbilical discharge (shaggy unhealthy umbilical stump, malodorous or purulent discharge); category 2, omphalitis with abdominal wall cellulitis (periumbilical erythema and superficial tenderness in addition to findings in category 1); category 3, omphalitis with systemic sepsis; and category 4, omphalitis with fasciitis (umbilical necrosis with extensive local disease, periumbilical ecchymosis, crepitus bullae, and evidence of involvement of superficial and deep fascia) [224].

Cultures of umbilical tissue in all categories of infection often yield several organisms, including *S. aureus* and CA-MRSA [211,225]. Management of categories 1 through 3 is usually with aggressive local care and systemic, broad-spectrum antibiotic therapy active against enteric bacilli, anaerobes, and *S. aureus*, with an option to provide oral therapy only for infants in category 1 if close observation and frequent reexamination can be arranged.

The most life-threatening entity, necrotizing fasciitis, requires immediate administration of broad-spectrum antibiotics and supportive care, with aggressive surgical débridement. Because *S. aureus* may be just one of several pathogens cultured, the exact role of *S. aureus* in the overall clinical disease process cannot be accurately assessed. Of seven infants presenting at 4 to 14 days of age with necrotizing fasciitis in Los Angeles, California, four were culture-positive for *S. aureus* in a mixed infection [226]. In Muscat, Oman, 10 of 14 neonates had *S. aureus* cultured from umbilical tissue, including 1 infant positive for MRSA, with 3 of the 10 infants having concurrent staphylococcal bacteremia [227]. Despite aggressive management, the mortality rates of polymicrobial necrotizing fasciitis have been 60% to 70% from sites in the United States [226,227], suggesting that earlier recognition with aggressive surgical management, critical care support, and antimicrobial therapy that includes activity against *S. aureus* or CA-MRSA if appropriate may be necessary to improve outcomes.

Necrotizing fasciitis caused solely by MRSA in the newborn is extremely unusual. The report of the first three cases from the Chang Gung Children's Hospital in Taiwan in 1999 [228] did not include information on the molecular characterization of these strains, raising the possibility that these MRSA strains may not be similar to the currently prevalent USA300 pulsotype, PVL-positive CA-MRSA strains. The clinical course of extensive soft tissue necrosis with relatively mild systemic symptoms, no mortality, and hospital discharge after 3 to 4 weeks of hospitalization is consistent, however, with current reports of CA-MRSA necrotizing fasciitis in 14 adults in Los Angeles and reports of single cases in neonates from San Diego, California, and Chicago, Illinois [229–231].

These neonates present for medical attention at 5 to 16 days of age with acute development of symptoms over 24 to 48 hours and rapid spread of erythema with indurative edema of infected tissues that have not been known to be previously traumatized. The infants may appear systemically ill with fever, irritability, and a laboratory evaluation suggesting acute inflammation with elevated peripheral white blood cell count, C-reactive protein, and frequently blood culture that is positive for *S. aureus*. Although imaging should not delay emergent surgical débridement, magnetic resonance imaging (MRI) is the preferred modality in adults, and presumably infants, to define the soft tissue characteristics of necrotizing fasciitis [232,233]. In addition to broad-spectrum antimicrobials outlined previously and surgical débridement, hyperbaric oxygen treatment has been used, but its role is poorly defined, with no prospective, randomized clinical trial data and only single cases or small case series that may or may not support adjunctive hyperbaric oxygen therapy [228,233,234].

## STAPHYLOCOCCAL SCALDED SKIN SYNDROME AND BULLOUS IMPETIGO

SSSS has been reported in full-term and premature infants [235–239]. The first series of patients in 1878 from Prague by Ritter von Rittershain [240] described clinical infection that is likely to have included patients with SSSS. Clinical characteristics in neonates are similar to characteristics in infants and older children [241] with acute onset of infection associated with macular or generalized erythema usually starting on the face and moving to the trunk within 24 hours. Erythema is accentuated in the flexor creases of the extremities, similar to streptococcal toxin disease, but with minimal mucous membrane erythema. Within 48 hours, the involved tender skin, primarily on the face, diaper area, and extremities, begins to form superficial, clear, flaccid bullae that subsequently break, revealing bright red, moist skin. These lesions show a separation of tissue layers within the epidermis, at the junction of the stratum spinosum and stratum granulosum, owing to the effect of staphylococcal exfoliative toxins A and B on desmoglein-1 (see "Pathogenesis of Disease").

The characteristic histologic feature of SSSS is intraepidermal cleavage through the granular layer, without evidence of epidermal necrosis or inflammatory cell infiltrate (Fig. 14–7) [242]. This appearance is distinct from the appearance in toxic epidermal necrolysis, which is characterized by a subepidermal split-thickness and full-thickness necrosis of the epidermis. Desquamation may be local, under the bullae, or generalized (Fig. 14–8). Before formation of bullae, erythematous skin shows intraepidermal separation when gentle tangential pressure is applied (Nikolsky sign), resulting in blister formation. These cutaneous findings may occur in the context of low-grade fever in about 20% of infants. Given the relatively high layer of epidermis involved, no major clinical sequelae occur because there are no substantial fluid, electrolyte, or protein losses, in contrast to erythema multiforme involving the dermal-epidermal junction. After appropriate antimicrobial therapy, the denuded skin dries within the subsequent few days and, in the absence of superinfection, heals completely within a few weeks with no scar formation.

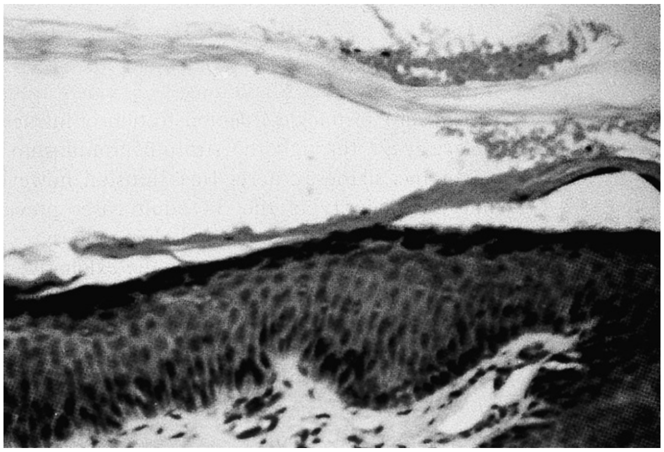

**FIGURE 14–7 Photomicrograph of skin biopsy specimen from a patient with staphylococcal scalded skin syndrome, stained with hematoxylin and eosin.** Histologic appearance is characterized by epidermal splitting at the granular layer of the epidermis. (Magnification approximately 200×.) *(From Hardwick N, Parry CM, Sharpe GR. Staphylococcal scalded skin syndrome in an adult: influence of immune and renal factors. Br J Dermatol 132:468-471, 1995.)*

Localized staphylococcal infection leading to SSSS may also occur with wound infections, cutaneous abscesses, or conjunctivitis [237,239]. Bacteremia is rare with SSSS, but has been reported [243,244]. Although infection is most commonly described in full-term neonates during the first few months of life, infections in premature infants, including infants with extremely low birth weight, have also been described [235–238]. Scarlatina, as the only clinical manifestation of infection caused by an epidemic strain of SSSS-causing *S. aureus*, has also been observed [239].

Congenital SSSS infection, acquired before delivery as a function of maternal amnionitis, has also been reported in term [244,245] and preterm [246] infants, with a mortality rate that may be higher than the extremely low rate documented for disease acquired postnatally. Outbreaks of disease among hospitalized infants in nurseries have occurred, but most have been effectively stopped with standard infection control practices [239,247].

## PNEUMONIA

Neonatal pneumonia caused by *S. aureus* has been described for decades, often reported to occur in community epidemics in infants during the first month of life. These infections, even before the advent of CA-MRSA, have been known to cause severe disease with a high mortality rate that may reflect virulence of strains circulating at that time [160,248,249].

In the current era, staphylococcal pulmonary infections produce many different clinical syndromes, depending on the pathogen and presence or absence of underlying lung disease and other comorbidities. The severity of infection caused by CoNS, as with all staphylococcal site-specific infections, is less than that caused by MSSA or CA-MRSA. A lower respiratory tract infection may occur as a primary pneumonia as the sole clinical manifestation of infection caused by *S. aureus*, with acquisition of the organism after contact with family members or hospital staff. Pneumonia may also occur as part of more generalized, invasive, disseminated staphylococcal infection. In large series of neonatal sepsis and bacteremia cases, pneumonia caused by either CoNS or *S. aureus* is only rarely listed as a primary diagnosis, or a complication, without details provided about the clinical presentation of lower respiratory tract disease [6,161–163,175]. The infection is often hospital-acquired in a neonate with underlying lung disease, most commonly chronic lung disease (bronchopulmonary dysplasia), especially in infants receiving concurrent mechanical ventilation.

An early study of staphylococcal pneumonia in the first month of life was reported from New Zealand in 1956 during an epidemic that primarily caused cutaneous infection. The eight infants who died of pneumonia in this epidemic presented at 2 to 3 weeks of age with irritability and poor feeding noted for a few days, followed by dyspnea, cough, and fever [248]. Death occurred in these infants 1 to 5 days

**FIGURE 14–8 Generalized staphylococcal scalded skin syndrome in previously well newborn infant. A** and **B**, Characteristic well-demarcated erythematous superficial exfoliation, with areas of skin sparing, can be seen. *(From Ladhani S, et al. Clinical, microbial, and biochemical aspects of the exfoliative toxins causing staphylococcal scalded-skin syndrome. Clin Microbiol Rev 12:224-242, 1999.)*

after admission, with autopsy findings documenting empyema, consolidation, and abscess formation. In a study of community-acquired *S. aureus* infection in neonates from Houston, Texas, from 2001-2005, infants were described who had no underlying disease, no indwelling catheters, and no previous hospitalization. Of 89 neonates identified with *S. aureus* infection, only 1 had a primary lung infection, caused by CA-MRSA, producing a necrotizing pneumonia complicated by pneumothorax and empyema and requiring video-assisted thoracoscopic surgery and chest tube drainage.

Other cases of severe CA-MRSA neonatal pneumonia have been reported, including hospital-acquired infections in premature neonates [25,168,250]. In hospitalized neonates with bacteremia with CA-MRSA in Houston, two of eight had lung involvement: a 24-week gestation 14-day-old infant with empyema, pneumatoceles, and concurrent endocarditis and a 28-week gestation infant with multiple comorbidities including bronchopulmonary dysplasia with infection acquired at 411 days of age, characterized by lung abscess. Both infants died. At present, these cases are uncommon, but they seem to be increasing. The striking severity of CA-MRSA pulmonary disease in the neonate with an extremely high mortality rate despite adequate antimicrobial therapy and supportive care is of great concern. Accurate data on the population-based rates of *S. aureus* pneumonia in neonates are currently unavailable.

In a point-prevalence survey of neonatal infections in 29 Pediatric Prevention Network NICUs in the United States and Canada, 116 NICU-acquired infections were reported: 15 (13%) were respiratory associated, virtually all in infants with birth weights of 501 to 1500 g; only 2 were associated with CoNS, and only 1 was associated with *S. aureus* [161]. In a review of invasive staphylococcal infections of hospitalized neonates admitted to level II or level III nurseries in Houston, 3 of 41 infants with *S. aureus* infection and 14 of 108 with CoNS infection were documented to have pneumonia. In this population, many had comorbidities, including respiratory distress syndrome in 85% of neonates ultimately diagnosed with any invasive *S. aureus* infection and in 95% of neonates with CoNS. Similarly, bronchopulmonary dysplasia was documented in 65% of *S. aureus*–infected infants and 75% of infants infected by CoNS. In this series, no infant with *S. aureus* pneumonia was documented to develop pneumatoceles or empyemas in the course of infection [178]. The Australasian Study Group for Neonatal Infections collected data on infants with documented bacteremia, occurring at 48 hours to 30 days of age. Of 1281 episodes of CoNS bacteremia, only 6 (0.5%) were documented to have pneumonia [162], in contrast to 223 with MSSA bacteremia associated with 9 (4%) cases of pneumonia and 65 cases of MRSA bacteremia associated with 8 (12%) cases of pneumonia [163].

## MENINGITIS

Meningitis is infrequently encountered in neonates with *S. aureus* bacteremia [178,210,211], but may be found when a lumbar puncture is performed even after empirical antibiotic therapy has been started. In a large series of 90 episodes of MRSA bacteremia in neonates in a Taiwanese NICU, 2 were noted to have meningitis [180]. In a report from Australia and New Zealand, meningitis was reported in 5 of 223 infants with MSSA bacteremia (2.2%) and 3 of 65 infants with MRSA bacteremia (5%) [162]. In most reports in which cerebrospinal fluid white blood cell counts are provided, they are often less than 200 cells/mm$^3$, however, suggesting that these infants with a cerebrospinal fluid pleocytosis and negative cerebrospinal fluid cultures may not have true staphylococcal bacterial meningitis. Virtually no infant from any series had a positive cerebrospinal fluid culture for *S. aureus*, including 12 infants with bacteremia with a documented pleocytosis from Texas Children's Hospital [211]. It is possible that the pleocytosis represents the entry of staphylococcal cell wall components or inflammatory mediators into cerebrospinal fluid during bacteremia, perhaps facilitated by capillary leak that often accompanies staphylococcal sepsis. Other possibilities include very early bacterial meningitis or a staphylococcal parameningeal focus of infection that was not identified in infants or included in the reports.

In a report from the Australasia Study Group data, of 1281 episodes of CoNS sepsis, 5 (0.4%) were reported to be associated with meningitis [162]. An additional two cases were reported in premature infants from another institution, born at 24 weeks and 25 weeks of gestation, one with a grade IV intraventricular hemorrhage. Multiple cultures in both infants confirmed infection caused by *S. epidermidis* in one infant and *S. capitis* and *S. warneri* in the other infant [251].

## BRAIN ABSCESS

Brain abscesses caused by *S. aureus* have been described in neonates, most often as a complication of sepsis [252–254]. Clinical presentation includes nonspecific symptoms of systemic infection and a bulging fontanelle; focal neurologic deficits may not occur. The key to diagnosis includes ultrasound or computed tomography (CT) of the head with administration of an intravenous contrast agent and, if not contraindicated, an evaluation of lumbar cerebrospinal fluid. Surgical drainage of the abscess is usually done followed by prolonged antistaphylococcal therapy. Long-term outcome has included neurologic deficits of varying degrees.

Neonates with intraventricular hemorrhage, acute hydrocephalus, congenital malformation, or central nervous system parenchymal injury often require management of increased intracranial pressure by repeated lumbar puncture or by placement of a shunt originating in the cerebrospinal fluid ventricles [255,256]. CoNS are the most common organisms to infect shunt material, producing mild to moderate inflammation and systemic signs and symptoms of infection [255–259]; occasional infection caused by *S. aureus* has also been reported [256,259]. Shunt removal is the preferred method of treatment because sterilization of in situ shunt material is often quite difficult [257]. Treatment with high-dose systemic antimicrobials active against the isolated pathogens, usually vancomycin, 3 to 10 days after shunt removal is recommended, depending on the clinical status and the microbiologic response to treatment. Some authors also recommend using intraventricular vancomycin therapy if therapeutic ventricular cerebrospinal fluid concentrations cannot be achieved with systemic therapy [257,260,261]. The role of linezolid in the treatment of shunt infections remains to be defined, but may represent an option for CA-MRSA strains that are not fully susceptible to vancomycin [262]. Although CoNS infections are seldom associated with acute toxicity or mortality, management with long-term antibiotic therapy and repeated surgical interventions for removal and placement of shunts each carry risks to the neonate.

## OSTEOARTICULAR INFECTION

Bone and joint infection has long been known to occur with invasive staphylococcal infection in the neonate, with rates of late sequelae of 50% [263–268]. In contrast to infections in older children, the usual distinction between infection of the bone and infection of the joint in a neonate is not as easily made because of the unique neonatal anatomy, with easy spread of organisms initially inoculated into metaphyseal bone through transphyseal vessels into the epiphysis and subsequently into the joint [269,270]. In addition to decompression of metaphyseal bone infection into the adjacent joint, erosion through the thin cortical bone may also occur, creating subperiosteal abscesses and subsequent involvement of the soft tissues of the extremity [263,269,271]. Virtually all reported cases have been caused by *S. aureus*, although more recent reports document the occurrence of CA-MRSA as a cause of neonatal osteomyelitis [268,272].

The clinical presentation of neonatal bone and joint infections seems to take three general forms. First, the infection may be secondary to staphylococcal sepsis with bacteremia in which case the focal bone and joint findings may not be the most prominent presenting symptom, but bone and joint sequelae of bacteremia become more apparent as the systemic infection is treated [163,268]. Second, and probably most common, an occult bacteremic inoculation of bone may occur, leading to either a single site or, in up to 50% of infants, multiple sites of infection [267,268,272]. In these infants, the clinical findings may be subtle and include signs of irritability, swelling around the affected bone or joint or both, and occasionally failure to move the limb (pseudoparalysis); fever may or may not be present [268,273,274]. Risk factors for bacteremia in these infants include umbilical artery catheterization and prematurity [266–268,275]. In bacteremic disease, the femur and tibia are the most prominently involved bones, infected in approximately 80% of all cases of osteomyelitis [266–268]. Adjacent joints may be involved clinically in 25% to 50% of cases, although in an autopsy review of staphylococcal osteomyelitis, all infants with bone infection were documented

on pathology to have adjacent arthritis [266,268–270]. Because most data are from small case series, accurate data on the presenting signs and symptoms may reflect strains circulating in a region at a particular point in time or may be related to outbreaks of specific strains [163]. Because of delays in diagnosis of osteomyelitis, the location of the infection that often involves bone on both sides of the physis, and frequent involvement of the adjacent joint, late sequelae are common after bacteremic infection; 50% of infants may have long-term sequelae, including limb shortening and decreased range of motion [265–267].

A third clinical scenario leading to a bone or joint infection may be specifically linked to trauma. Osteomyelitis of the calcaneus has been documented to occur as a complication of heel-stick blood sampling, most often manifesting with focal swelling, erythema, and drainage [276]. More recent reports cite continuing problems secondary to a single heel-stick that is used for metabolic screening in all newborns [277]. Fetal scalp monitoring has been associated with skull osteomyelitis [278]. Pyogenic arthritis of the hip is a reported complication of femoral vein venipuncture [279].

Bone radiographs can show destructive changes in the bone becoming apparent in the 2nd week of infection. In the case of arthritis, widening of the joint space and bulging of the soft tissues may be seen as a clue to diagnosis. Ultrasound may identify collections of pus that are subperiosteal or in the soft tissues. Although radionuclide bone scanning with technetium-99m may provide additional useful information regarding the involvement of multiple bones, the normal increased vascularity of the neonatal metaphysis may blur the differentiation between infection and increased uptake that is commonly seen in osteomyelitis in older children. Decreased blood flow from necrotic injury to the bone may lead to false negative test results in the newborn. MRI is becoming the preferred imaging modality, based on excellent visualization of soft tissues and bone with a lack of ionizing radiation. MRI may be too sensitive, however, in assessment of tissue inflammation in bones and soft tissues adjacent to the infected site, suggesting a greater extent of infection than is actually present. MRI with contrast agent provides additional information on inflammation in bones and soft tissues and may be particularly helpful when imaging the spine to detect vertebral osteomyelitis or diskitis. CT of neonatal bones and joints has a more limited role in diagnosis of acute infection.

## INFECTIONS OF THE GASTROINTESTINAL TRACT

*S. aureus* is a common colonizer of the gastrointestinal tract of newborns, present in up to 93% of asymptomatic infants [280]. The prevalence of colonization is not surprising, considering that *S. aureus* organisms can be recovered from samples of breast milk [281].

Infections of the gastrointestinal tract can be caused by one of the enterotoxins produced by *S. aureus* or can be a manifestation of invasion of the mucosa resulting in enterocolitis [282]. Although *S. aureus* has been described to colonize the gastrointestinal tract in the absence of clinical disease [280], certain poorly defined risk factors may place colonized infants at risk of invasive disease, including feeding tubes and previous antibiotic therapy that may have facilitated colonization with *S. aureus* [283]. Clinical presentation includes signs and symptoms of generalized sepsis in association with frequent, blood-tinged, thin, mucus-containing diarrheal stools. A report of neonatal staphylococcal enterocolitis caused by MRSA described a need for therapy with intravenous and oral vancomycin to establish a microbiologic cure for the systemic infection and colonization; the infant ultimately developed colonic stricture as a late complication of infection [284]. Delta toxin–producing-CoNS [285] and MRSA [286] have not been confirmed to have a major role in the pathogenesis of neonatal necrotizing enterocolitis, although they may have a supporting role in the disease process in some infants.

## DIAGNOSIS

In the previously cited reports on clinical manifestations of staphylococcal infection, diagnosis has most often been made by direct culture of the infected tissues or abscesses if the disease is focal or by cultures of blood, urine, or cerebrospinal fluid for diagnosis of sepsis and bacteremia, pyelonephritis, or meningitis and shunt infection. Organism identification and susceptibility testing are essential in understanding the organism-specific severity of disease and provide information on appropriate antimicrobial therapy. In addition, having the laboratory save the neonate's isolate allows one to compare subsequent episodes of infection by that organism in that infant or compare episodes of infection by the organism that may have spread to or from other neonates.

The diagnosis of infection by nonspecific laboratory tests that assess inflammation in the infant being evaluated can provide supportive evidence for infection. A detailed evaluation of specific tests, such as total white blood cell count, immature neutrophil (band-form) count, mature-to-immature white blood cell ratio, C-reactive protein, procalcitonin, cytokines (IL-6, IL-8, IL-10, TNF-α) [287–291], and chemokines [292,293] (interferon-γ-inducible protein-10, monocyte chemoattractant protein-1, RANTES, epithelial neutrophil activating peptide-78), is beyond the scope of this chapter. The sensitivity, specificity, and positive predictive values vary with the investigating institution and the population of neonates studied; some laboratory test results become abnormal within a few hours of the onset of infection, whereas others may not increase for 1 to 2 days.

Rather than a single test, a set of tests may offer the best hope for diagnosing early infection and tracking the response to therapy [293,294]. At the present time, C-reactive protein and procalcitonin seem to be among the most useful and the most widely available tests for assessment of neonatal sepsis. Some studies have suggested the usefulness of an elevated immature-to-total neutrophil ratio in identifying infants with CoNS septicemia [295–297]. No test has the ability to identify all infected infants, with decisions on further investigation and empirical antimicrobial therapy still requiring clinical judgment. With more premature and younger infants, the interval is greater from the time of infection to the time of

a positive nonspecific test for inflammation. MSSA and MRSA *S. aureus* seem to generate far more vigorous responses than CoNS. These nonspecific tests of inflammation should not play a decisive role in the determination of whether a single positive blood culture for CoNS represents a true positive culture or a contaminant.

Multiple positive blood cultures for the same strain of CoNS in a relatively asymptomatic infant may provide evidence of true infection that is more reliable than the white blood cell count or any inflammatory marker. Polymerase chain reaction techniques to detect 16S-rRNA in plasma followed by specific probes for *S. aureus* and CoNS show promise, but cannot currently be used as the sole diagnostic test for staphylococcal infection [298]. Emerging non–culture-based diagnostic methodologies for neonatal infection are evaluated in detail in Chapter 36.

# ANTIBIOTIC TREATMENT

See also Chapter 37.

## GENERAL PRINCIPLES

Optimal treatment for staphylococcal infections in neonates is designed to achieve an appropriate antimicrobial exposure at the site of infection and surgical control of the infection by drainage of any abscess and removal of any potentially infected foreign material. As with all neonatal bacterial infections, cultures of appropriate samples, based on signs and symptoms of infection, physical examination, and imaging, should provide the necessary information regarding the identity and susceptibility pattern of the pathogen. The choice of empirical therapy, before susceptibility test results are known, depends on the local antibiotic resistance patterns for coagulase-positive and coagulase-negative staphylococci, the severity of infection, and the toxicity profile of the antibiotic for that infant.

For CoNS, susceptibility patterns are quite varied and are often based on the particular species isolated. For coagulase-positive strains, it is essential to know the susceptibility to β-lactamase–stable penicillins. Culture and susceptibility information has a direct impact on selection of definitive therapy, allowing the use of the most narrow-spectrum, least toxic antimicrobial regimens.

Although β-lactam agents are preferred for treatment of infections with MSSA in the neonate because of their bactericidal activity and overall safety, several other clinically useful classes may also show in vitro activity, including glycopeptides, aminoglycosides, lipopeptides, oxazolidinones, lincosamides, rifamycins, and trimethoprim-sulfamethoxazole. As with so many other drugs for neonates, adequate prospective data on the safety and efficacy of these antimicrobials for the various tissue sites of infection caused by CoNS, MSSA, and MRSA are unavailable. Extrapolation from other pediatric and adult data is necessary, with cautions for the neonate on outcomes at dosages suggested and on the safety of these antimicrobials.

For antimicrobial therapy of *S. aureus* infections, infections should be separated into MSSA and MRSA. Among MRSA, further differentiation should be made between the more antibiotic-resistant hospital-acquired strains (HA-MRSA) and community-acquired strains (CA-MRSA). No MRSA strains can be killed by penicillin or ampicillin, β-lactamase–stable antistaphylococcal penicillins (methicillin, nafcillin, oxacillin, dicloxacillin), currently available cephalosporins (cephalexin, cephalothin, cefazolin, cefuroxime, cefotaxime, ceftriaxone), or carbapenems (meropenem, imipenem, ertapenem, doripenem). HA-MRSA strains carry relatively large antibiotic resistance gene cassettes with concurrent resistance to clindamycin, macrolides (erythromycin, clarithromycin, and azithromycin), and aminoglycosides, a resistance profile that is usually not seen in CA-MRSA strains.

For mild to moderate invasive staphylococcal infections in neonates in areas of the world where methicillin resistance is still minimal, empirical therapy with first-generation cephalosporins (parenteral cefazolin, oral cephalexin) or antistaphylococcal penicillins (parenteral methicillin, oxacillin, or nafcillin) is preferred. In some cases of mild skin infection, topical antibiotic therapy with mupirocin may suffice. For mild to moderate infections in areas where CA-MRSA occurs at substantial rates (≥5% to 10%), clindamycin or vancomycin intravenously should be used empirically until susceptibility data are available. If clindamycin is used, caution should be exercised in treating erythromycin-resistant, clindamycin-susceptible strains of *S. aureus* with clindamycin because those strains may display inducible clindamycin resistance (see "Clindamycin and Erythromycin" subsequently). The role of oral therapy for neonatal staphylococcal infections is not yet well defined. For MRSA strains that are susceptible, erythromycin, azithromycin, and clindamycin may be considered for mild infections, or step-down therapy may be considered in newborns who have responded well initially to intravenous therapy. Trimethoprim-sulfamethoxazole may be considered for mild infections in infants who no longer exhibit physiologic jaundice.

For serious infections in neonates in regions of the world in which CA-MRSA is routinely isolated, empirical therapy with vancomycin is preferred over clindamycin, given the bactericidal nature of killing and extensive experience with vancomycin in newborns. For suspected *S. aureus* infections that are nosocomially acquired within institutions in which MRSA is present in other neonates, empirical therapy with vancomycin for presumed MRSA is also recommended. With data suggesting that the most common pathogen responsible for bloodstream infections in late-onset sepsis in hospitalized neonates is CoNS, most often resistant to β-lactam antibiotics, vancomycin is likely to provide effective therapy. For situations in which cultures show MSSA or methicillin-susceptible or penicillin-susceptible CoNS, it is imperative that therapy be switched back to traditional β-lactam antibiotics to minimize antibiotic pressure on staphylococcal species from vancomycin or clindamycin, to delay the emergence of resistance to these antibiotics. β-lactam antibiotics are generally less toxic to the neonate compared with vancomycin and clindamycin and are better tolerated.

## VANCOMYCIN

Vancomycin is a first-generation bactericidal glycopeptide antibiotic. Vancomycin normally inhibits growth of the organism by binding to cell wall precursors, inhibiting

transglycosylase function and cell wall synthesis. Complete resistance to vancomycin is relatively recent and quite limited, with the first cases of complete resistance having been reported in 2002. Within every population of *S. aureus*, a very low frequency of organisms with intermediate resistance to vancomycin exists, however, and these organisms may become selected out in infants with prolonged exposure to vancomycin. By contrast, complete vancomycin resistance is still exceedingly rare and created by a different mechanism that parallels vancomycin resistance in enterococci.

Dosing of vancomycin is designed to achieve an area under the curve-to-minimal inhibitory concentration ratio (AUC:MIC) of approximately 250 and is associated with microbiologic cure in experimental in vitro and in vivo animal models and in retrospective analyses of infections in adults [299]. In neonates, many dosing recommendations exist, including intermittent dosing and continuous infusion, primarily based on chronologic and gestational age and based on serum creatinine [300–304]. An initial loading dose of 15 mg/kg is most often recommended, followed by repeated dosing every 8 to 24 hours, reflecting longer dosing intervals for the youngest, most premature infants. Each dose should be administered over 60 minutes. Close monitoring of renal function and serum concentrations of vancomycin are recommended in all neonates receiving therapy, allowing for adjustment of vancomycin dosing regardless of the initial empirical dosing regimen chosen. Intraventricular vancomycin has been used to treat central nervous system infections, primarily ventriculoperitoneal shunt infections caused by CoNS [260,261], although cerebrospinal fluid concentrations may be therapeutic after intravenous administration [301].

## CLINDAMYCIN AND ERYTHROMYCIN

Clindamycin, a lincosamide, and erythromycin, a macrolide, inhibit ribosomal function and produce a primarily bacteriostatic effect by binding to sites on the ribosome. Most strains of MSSA remain susceptible to clindamycin and erythromycin. Many strains of CA-MRSA remain susceptible, but most strains of HA-MRSA and CoNS are resistant to these antibiotics. Staphylococcal resistance to erythromycin may occur by two mechanisms: by methylase-mediated dimethylation of the 23S ribosomal binding site of the macrolides and by the presence of an efflux pump that expels the macrolide from the intracellular environment of the pathogen. The methylase gene, *erm*, is usually inducible, but in any large population of organisms, mutants occur that constitutively produce methylase, providing complete resistance to all macrolides (erythromycin, azithromycin, clarithromycin), clindamycin, and streptogramins (quinupristin-dalfopristin).

By contrast, the most prevalent macrolide efflux pump for staphylococci, *msrA*, does not recognize, bind to, or eliminate clindamycin from within the bacteria, allowing these strains to remain susceptible to clindamycin. Any strain that shows in vitro erythromycin resistance and clindamycin susceptibility must also be tested for methylase-mediated clindamycin resistance by an additional assay, the D-test. Current laboratory reporting guidelines suggest that hospitals report erythromycin-resistant, D-test–positive strains as clindamycin-resistant, on the basis of reported clinical failures of clindamycin in treating infections caused by inducible organisms. Because the true clinical significance of inducible *erm*-mediated resistance for clindamycin is not well defined at present, it is prudent to use other antibiotic options for a seriously ill neonate with infection caused by a D-test–positive strain.

Erythromycin is associated with the occurrence of pyloric stenosis in the newborn infant, a side effect that is likely to be less prevalent in clarithromycin and azithromycin. Clindamycin, erythromycin, and azithromycin are available in oral and intravenous formulations, but little prospective, comparative data exist for their use in neonates.

## LINEZOLID

Of the antibiotics approved during the past decade with activity against MRSA, linezolid is the only one currently approved by the U.S. Food and Drug Administration (FDA) for use in neonates. As might be predicted, resistance to linezolid has been documented to develop in adults receiving therapy for a bacteremic MRSA infection, although to date resistance remains rare [305]. Linezolid is an oxazolidinone-class protein synthesis inhibitor, the first of this new class of antibiotics. Linezolid is a ribosome-inhibiting, bacteriostatic agent, active against coagulase-positive and coagulase-negative staphylococci. Data on pharmacokinetics are available for all pediatric age groups, including premature neonates less than 34 weeks' gestational age.

Linezolid can be administered intravenously and orally, with virtually 100% of the agent absorbed by the oral route. Protein binding in plasma is approximately 30%, and the drug is well distributed into tissues. Linezolid is cleared by the kidneys, unchanged and after oxidation of the parent compound. Because oxidation of linezolid does not depend on renal function, no dose reduction is needed for renal insufficiency. Linezolid has been studied in neonates and older children for nosocomial and community-acquired pneumonia and for complicated and uncomplicated skin and skin structure infections [306,307]. The clinical response rates for each of these tissue-specific infections were equivalent to comparator agents, usually vancomycin. The pathogen-specific response rates for infections caused by *S. aureus*, including MSSA and MRSA strains, and response rates for infections caused by CoNS were also statistically equivalent to vancomycin. Similarly, the rates for clinical and laboratory adverse events were equivalent to adverse events in vancomycin-treated control patients. In neonates and children enrolled in these registration trials, the hematologic toxicity profiles for neutropenia and thrombocytopenia were equivalent to vancomycin. These data suggest that hematologic toxicity of thrombocytopenia and neutropenia seen in adults may not be seen as frequently in neonates and children.

Recommendations for the dosage regimen for preterm neonates less than 7 days of age (gestational age <34 weeks) are based on data from registration trials involving very few neonates. Preterm neonates should be initially

given 10 mg/kg every 12 hours. For neonates with a poor response to infection caused by a susceptible organism, an increased dose of 10 mg/kg every 8 hours can be provided. By 7 days of age, all neonates, regardless of gestational age, should receive 10 mg/kg every 8 hours. The interpatient variability in neonates was noted to be greater than that seen in adults and may reflect variation in the rate of maturation of mechanisms of elimination.

In studies of cerebrospinal fluid linezolid concentrations in infants with ventriculoperitoneal shunts receiving systemic therapeutic dosing, adequate concentrations were not consistently achieved. Although a case report exists for the treatment of a staphylococcal central nervous system infection in a neonate [262], the routine use of linezolid for the treatment of central nervous system infections cannot be recommended at this time. Similarly, case reports on the treatment of neonatal endocarditis caused by MRSA exist, but the safety and efficacy of linezolid for this indication remain to be defined. The role of combination therapy using linezolid is also not defined.

## DAPTOMYCIN

An antibiotic approved only for use in adults, daptomycin is a novel lipopeptide bactericidal agent for gram-positive organisms, including *S. aureus* and CoNS. Structurally, daptomycin is a 13-amino acid cyclic peptide with a lipophilic tail that inserts into the cell membrane, leading to depolarization of the membrane, inhibition of protein, DNA, and RNA synthesis, and cell death. Daptomycin shows concentration-dependent killing pharmacodynamics. It is available only in an intravenous formulation. Pharmacokinetic studies are ongoing in older children, but no data exist for neonates. The prolonged half-life in adults of 8 to 9 hours allows for once-daily dosing. The antibiotic is highly protein bound (90%) and is excreted primarily by the kidney with little degradation of the parent compound. In renal insufficiency, the dose is decreased according to the degree of renal failure.

In adults, daptomycin is approved by the FDA for the treatment of complicated skin and skin structure infections (caused by *S. aureus*, including MRSA) and for bacteremia and endocarditis. Daptomycin also shows in vitro activity against vancomycin-resistant *S. aureus* and should represent an effective agent if these strains become more widespread. Daptomycin is not indicated for the treatment of pneumonia because surfactant binding to the antibiotic is associated with inactivation. Myopathy is a potential adverse event, which was noted in early phase 1 studies, but with once-daily dosing in adults, no muscle toxicity was documented. Current guidelines suggest monitoring serum creatine phosphokinase concentrations weekly.

## QUINUPRISTIN-DALFOPRISTIN

Streptogramins are antibiotic derivatives of natural products of *Streptomyces pristinaespiralis*. Two streptogramins, quinupristin and dalfopristin, when used together in a fixed combination have been shown to be bactericidal against many gram-positive organisms, including staphylococci and certain enterococci. Each antibiotic is bacteriostatic, but when used together in a 30:70 ratio, the combination is bactericidal. The combination is approved by the FDA for adults as Synercid, for the treatment of vancomycin-resistant *Enterococcus faecium* infections and for the treatment of skin and skin structure infections caused by *S. aureus* (only MSSA strains were isolated from study patients). In vitro, quinupristin-dalfopristin is also active against MRSA and vancomycin-resistant *S. aureus*, although no clinical data are available for treatment of these infections. Quinupristin-dalfopristin is available only in an intravenous preparation. Both drugs are primarily eliminated through biliary excretion, with minimal metabolism. Inflammation and pain at the infusion site are substantial problems. Many mechanisms of bacterial resistance have been documented, ultimately limiting the clinical usefulness of this combination.

## COMBINATION ANTIMICROBIAL THERAPY

Although many combinations of antibiotics have been used in adults, few have been studied prospectively, with virtually no prospective comparative evaluations available for children and neonates. For invasive *S. aureus* disease, infective endocarditis in adults has resulted in some of the highest mortality rates, resulting in guidelines that recommend aggressive combination therapy based on animal model data, in vitro data, and data from CoNS infections [308]. For MSSA endocarditis, combination therapy with a β-lactam penicillin (oxacillin or nafcillin) and rifampin, plus the addition of gentamicin for the first 2 weeks of therapy, is believed to result in optimal microbiologic efficacy. For MRSA, vancomycin plus rifampin, with gentamicin for the first 2 weeks of therapy, should be considered [308]. A report on vancomycin plus rifampin combination therapy of persisting CoNS bacteremia after removal of a central catheter provides some support to this approach [309].

A Cochrane review of intravenous immunoglobulin therapy of suspected or documented neonatal sepsis evaluated nine clinical trials. Although substantial heterogeneity existed across studies in immunoglobulin preparations, dosing regimens, and populations studied, no substantial benefit was derived from treatment, particularly with respect to mortality in infants with either suspected infection or subsequently proven infection [310].

## CATHETER REMOVAL

The decision to remove an indwelling catheter from a neonate with bacteremia often is difficult, especially when securing subsequent intravascular access may be challenging. Delayed removal of a central catheter in the setting of bacteremia may be associated with an increased risk of infection-related complications [189]. For infants with CoNS bacteremia, successful treatment of bacteremia may be possible with the central venous catheter in situ [189]. If bacteremia persists for longer than 4 days, the chance for subsequent clearance is reduced [188], however, and the risk of end-organ damage may be increased [164,189]. The presence of a ventricular reservoir or ventriculoperitoneal shunt increases the chance of the development of meningitis in the setting of prolonged

catheter-related bacteremia. Prompt removal of an indwelling central venous catheter should be considered in infants with central nervous system hardware [188].

# PREVENTION

## HYGIENIC MEASURES

Major efforts to prevent staphylococcal infections in neonates, rather than being required to treat them, are of great value. General principles underlying nosocomial infection in the NICU and measures to reduce occurrence of infections that apply broadly to staphylococcal infections are discussed in detail in Chapter 35. Some specific considerations relevant to staphylococci are discussed briefly here.

Staphylococci may be spread through fomites; overcrowding of infants in the NICU may increase the risk of colonization and the potential for disease. In an outbreak situation, attempts to control the spread of staphylococci through remediation of overcrowding and isolation of infected or colonized patients have been shown to be effective in helping to curtail the outbreak, even in the case of MRSA [311].

A primary determinant of infant colonization is nursing care. Maintaining an appropriate nurse-to-infant ratio is an important factor in reducing disease when a disease-associated *S. aureus* strain gains entrance to a nursery, especially in the NICU [312]. In addition, various preventive maneuvers are directed at persons with direct infant contact, including frequent mask, gown, and glove changes before handling of infants [313,314]; application of antimicrobial or antiseptic ointment or spray [315,316]; and elimination of carriers from the nursery area [317,318]. In some situations, control of an epidemic requires removal of the nurse carrier from the nursery [319].

Currently, the U.S. Centers for Disease Control and Prevention recommends contact isolation for patients colonized or infected with MRSA [320]. This practice was shown to reduce nosocomial transmission of MRSA by 16-fold during an outbreak of MRSA in an NICU [321]. Several more recent publications have focused on nursery infection control measures, documented to be effective in preventing the entry of CA-MRSA into a nursery and its spread within the nursery [322–325].

In the early 1960s, attempts were made to stop virulent *S. aureus* epidemics in 10 NICUs throughout the United States using the technique of bacterial interference [326,327]. This technique involved deliberate implantation of *S. aureus* of low virulence (502A) on the nasal mucosa and umbilicus of newborns to prevent colonization with the virulent *S. aureus* strain. Although this procedure was successful in curtailing epidemics [328], it is not widely used or recommended currently.

Proper hand hygiene among nursery health care providers is a fundamental factor in reducing colonization rates. Mortimer and associates [329] achieved a reduction in infant colonization from 92% to 53% by insisting that attendants wash their hands. Proper education and monitoring of hand hygiene practices are critical to the effectiveness of this intervention [330,331]. Hands must be cleaned before and after patient contact or contact with equipment that is used for patient care. Hands also should be cleaned after glove removal. Proper hand hygiene involves applying alcohol-based waterless rubs if hands are not soiled [332] or washing the hands for at least 10 to 15 seconds with either chlorhexidine gluconate or triclosan hand-washing agents [333].

With the increase in prominence of CoNS as nosocomial pathogens, strategies for disease prevention have become increasingly important. As with *S. aureus*, strict hand hygiene is of primary importance in minimizing staff-to-patient and patient-to-patient spread of CoNS. In addition, meticulous surgical technique to limit intraoperative bacterial contamination is critical in minimizing infection related to foreign bodies. Strict attention to protocols for the insertion and management of intravenous and intra-arterial catheters may decrease the risk of catheter-related infections [334]. In patients who require intravenous access for prolonged periods, percutaneous placement of a small-diameter Silastic catheter is preferred when possible. In one study, these catheters were maintained for 80 days, with an infection rate of less than 10% in infants weighing less than 1500 g [335].

## ANTIBIOTIC PROPHYLAXIS

Investigational therapies to reduce neonatal bacteremia caused by staphylococci have been directed at the use of antibiotic prophylaxis and antibiotic-impregnated devices. Given the large burden of CoNS catheter infections in premature infants, investigations of prophylactic antibiotics to prevent infection were undertaken by many institutions, as reviewed more recently [336–340]. Vancomycin was documented to be successful in significantly decreasing the rate of suspected or documented sepsis caused by CoNS. Antibiotic-based methods to prevent bacteremic infection have included the use of a vancomycin solution (25 μg/mL) to dwell inside the infant's central venous catheter two to three times daily for up to 60 minutes [339]; the administration of low-dose vancomycin at 5 mg/kg twice daily [338]; or the addition of vancomycin to hyperalimentation solutions to a concentration of 25 μg/mL for routine administration. Although all three methods were successful at decreasing episodes of sepsis, the overall mortality in treatment versus control groups was not affected. Because of concerns for the emergence of vancomycin-resistant organisms, routine use of prophylactic vancomycin for all neonates at risk of CoNS bacteremia is not currently recommended. Potential risks associated with prophylactic vancomycin, including ototoxicity, nephrotoxicity, and selection for resistant bacteria, have not been well evaluated.

## IMMUNOPROPHYLAXIS

Studies evaluating the effectiveness of immunoglobulin preparations generally have not documented convincing, substantial benefits for the populations of premature infants studied [310]. These studies may reflect the lack of effectiveness of a specific biologic preparation, however, or suggest that particular subpopulations may benefit more from treatment than others, rather than proving that immunoglobulins have no potential role in

prophylaxis or treatment. Other polyclonal antibody approaches to prophylaxis in premature infants have used high-titer anti–*S. aureus* immunoglobulin (Altastaph), prepared from adult volunteers immunized with a staphylococcal vaccine. Pharmacokinetic, safety, and clinical outcome data in neonates randomly assigned to receive either immunoglobulin or placebo did not show benefit in early, limited trials [341].

Studies of monoclonal antibodies directed against specific staphylococcal epitopes are ongoing. A randomized, placebo-controlled trial was conducted in premature infants to prevent staphylococcal infection, using an intravenous immunoglobulin preparation selected from donors with high activity against specific staphylococcal fibrinogen-binding protein, ClfA, and Ser-Asp dipeptide repeat G (INH-A00021, Veronate). No benefit to prophylaxis was noted in the recipients of this staphylococcus-specific immunoglobulin [342,343]. An anti-staphylococcal monoclonal antibody, BSYX-A110, has been developed for the prevention of CoNS sepsis. This antibody targets staphylococcal lipoteichoic acid and has been shown to be safe and well tolerated when administered by intravenous infusion to high-risk neonates [344]. The efficacy of the antibody in preventing CoNS infections and related morbidity and mortality remains to be established.

Lactoferrin is an iron-binding glycoprotein present in breast milk that is believed to contribute to innate antibacterial immunity of the intestinal barrier, through a combination of restricting pathogen access to iron, cell wall lytic activity of its component peptides, and promotion of epithelial barrier maturation [345]. A randomized study of bovine lactoferrin supplementation in very low birth weight premature infants showed a promising reduction in the rate of late-onset sepsis in the treatment group (risk ratio 0.34, 95% confidence interval 0.17 to 0.70) [346].

## CONCLUSION

Staphylococcal infections result in significant morbidity and mortality in neonates. Although CoNS are frequent causes of less severe infections, the continuing relatively high rate of community-associated and hospital-associated infections caused by more aggressive *S. aureus* and the emergence of CA-MRSA with exceptionally high mortality rates have created an unprecedented need to understand the biology and mechanisms of virulence of staphylococci. With this understanding, we can generate improved approaches to prevent and treat infections. A profound need exists to develop more safe and effective antimicrobials and immunotherapies to mitigate the substantial morbidity and mortality caused by these pathogens.

## ACKNOWLEDGMENTS

The authors are indebted to Rachel C. Orscheln, Henry R. Shinefield, and Joseph W. St. Geme III, whose previous contributions to this chapter and clinical images provided the strong baseline framework and inspiration for the current version.

CHAPTER 15

# Gonococcal Infections

**Joanne E. Embree**

## CHAPTER OUTLINE

Infections of the fetus and newborn infant caused by *Neisseria gonorrhoeae* are restricted primarily to mucosal surfaces of the newborn infant. The most common condition related to infection by this organism during the neonatal period is ophthalmia neonatorum, or neonatal conjunctivitis. *N. gonorrhoeae* produces purulent conjunctivitis in the newborn that may lead to blindness if untreated. Ophthalmia neonatorum is the primary disease entity discussed in this chapter.

Ophthalmia neonatorum had been a well-recognized entity, affecting 1% to 15% of newborns, in Europe and North America when Hirschberg and Krause [1] first described neonatal infection caused by *N. gonorrhoeae* in an infant with purulent conjunctivitis in 1881. Shortly thereafter, the topical instillation of silver nitrate into the newborn's eyes immediately after birth dramatically reduced the incidence of this disease caused by *N. gonorrhoeae*, albeit with the complication in most infants of milder conjunctivitis, limited to the first 24 hours of life, owing to the silver nitrate itself [2,3]. Use of erythromycin or tetracycline ointments for this purpose has proved to be efficacious for preventing gonococcal ophthalmia, with markedly reduced problems related to the chemical conjunctivitis seen with silver nitrate [4–6]. Systemic neonatal infection is unusual, but infants may present with various clinical syndromes (in particular, arthritis), which implies that dissemination of the bacteria does occur [7,8].

Maternal systemic infection during pregnancy also is rare, and transplacental congenital infection of the fetus has not been described. Maternal genital mucosal infection may result in an ascending infection, however, with chorioamnionitis leading to premature rupture of the placental membranes and preterm delivery [9]. In developed countries, screening and treatment of pregnant women for gonococcal infections with tracing of named contacts, along with the use of neonatal ophthalmic prophylaxis, have substantially reduced the incidence of gonococcal ophthalmia neonatorum. In developing countries, improvements in access to medical care and aggressive pilot programs for prevention and treatment of sexually transmitted diseases (STDs) are additional public health measures of direct relevance. In conjunction with prevention strategies for human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS), such programs have continued to decrease the incidence of gonococcal infection and its complications, such as ophthalmia neonatorum, in areas where these interventions have been introduced [10]. Despite the overall decreasing prevalence of *N. gonorrhoeae* infection worldwide, however, gonococcal ophthalmia neonatorum remains a significant illness.

## EPIDEMIOLOGY AND TRANSMISSION

The incidence of neonatal gonococcal illness is related to the prevalence of *N. gonorrhoeae* colonization among women of childbearing age and to the rates of acute gonococcal infection during pregnancy. These numbers are quite variable worldwide and now are heavily influenced by the HIV-1 epidemic. Generally, when antibiotic treatment for gonorrhea became available in the mid-20th century, rates of infection among women decreased worldwide as these agents became more readily accessible and heath care programs improved. With the emergence of penicillin chromosomal resistance, the development of penicillinase production by some strains, and the expansion of the AIDS epidemic in the 1990s, however, rates began to increase again during that decade. In response, efforts to control this infection—which some authorities had hoped could ultimately be eliminated by the middle of the 21st century—have been increased.

Estimates by the World Health Organization of the burden of gonorrheal disease in various regions at the end of the 20th century are presented in Table 15–1 [11]. These estimates have not changed appreciably over the past decade, and although they are useful in indicating areas of high burden of disease, considerable variation within regions exists. This variation is reflected in the differences seen in the number of reported cases of gonorrhea among women in North America. In the United States during 2006, 358,366 cases of gonorrhea were tallied, resulting in a reported prevalence of 120.9 cases per 100,000 population, which was an increase of 5.5% over that reported in 2005 [12]. Previously, no significant changes had been noted in the prevalence rate among women in the United States during the past decade.

DOI: 10.1016/B978-1-4160-6400-8.00015-8

**TABLE 15–1** World Health Organization Estimated Numbers of Cases of Gonorrhea in Adults, 1999

| Geographic Location | Estimated No. Cases |
|---|---|
| North America | 1.5 million |
| Latin America | 7.5 million |
| Western Europe | 1 million |
| Eastern Europe and Central Asia | 3.5 million |
| East Asia | 3 million |
| South and Southeast Asia | 27 million |
| North Africa and the Middle East | 1.5 million |
| Sub-Saharan Africa | 17 million |
| New Zealand and Australia | 120,000 |

*Data from World Health Organization. Global prevalence and incidence of selected curable sexually transmitted infections: overview and estimates. WHO/CDS/CSR/EDC/2001 10:1–50, 2001.*

The prevalence among women has equaled that among men since 1998. Infection rates have decreased since 1986, when the prevalence among women was approximately 310 cases per 100,000 population. Further significant differences are noted among specific populations in the United States, however, when rates are compared for groups of different races or ethnicity and for location. The prevalence among blacks in the United States is still considerably higher than in other ethnic groups—at around 720 per 100,000 in 2006. The background prevalence also differs significantly among various regions of the United States, with higher rates of reported infections in the South and Midwest compared with the Northeast and West.

The United States has set a goal of reducing the national prevalence of gonorrhea to less than 19 cases per 100,000 among adults; however, that goal is unlikely to be met. Canada has placed an emphasis on STD control as well, but has an exclusively publicly funded health care system. Gonorrhea prevalence rates have decreased from 1980, when the prevalence among women was 166 per 100,000 population. The highest rates at that time were among women 15 to 19 years old and 20 to 24 years old, which were extremely high at 510 and 598 per 100,000. In 2007, the prevalence among women was approximately 28.6 per 100,000, which represents a significant increase from 1997, when rates were a low of 11 per 100,000. The increase has occurred primarily among women 15 to 19 years old and 20 to 24 years old; in these age groups, rates increased from 69 and 60 per 100,000 in 1997 to 167 and 148 per 100,000. In 1997, Canada had set as its goal the elimination of endemic transmission of *N. gonorrhoeae* by 2010 [13]. Similar to the United States, Canada is not expected to meet its elimination goals. The reasons for the rate increases are complex, but a proportion of the increase is likely related to the almost universal change in diagnostic procedures in Canada from culture to nucleic acid–based testing which is considerably more sensitive.

Factors that increase a pregnant woman's risk of acquiring *N. gonorrhoeae* infection are similar to the factors that increase the risk of acquisition of any other sexually transmitted infection [14]. The prevalence of *N. gonorrhoeae* in the population or network in which a woman socializes and chooses her sexual partners determines the likelihood of exposure to this pathogen. Women who have multiple sexual partners or whose partners have multiple sexual contacts increase their risk of exposure to *N. gonorrhoeae*. Women who do not use condoms or other barrier protection increase their risk of acquisition of *N. gonorrhoeae* infection on exposure to the organism. It is unknown whether women who are HIV-positive have an increased risk of infection by *N. gonorrhoeae* on exposure to it. Factors associated with an increased likelihood of at-risk behavior that results in an increased risk of gonococcal infection among pregnant women include younger age, unmarried status, homelessness, problems with drug or alcohol abuse, prostitution, low-income professions, and, in the United States, being black. Gonococcal infections are diagnosed more frequently in the summer months in the United States, probably reflecting transient changes in social behavior during vacations [15].

Varying gonococcal rates reported in various studies worldwide reflect the differences in risk among the populations studied. In a study in Brazil, involving a cross-sectional study of 200 women 14 to 29 years old who attended an HIV testing site in central Rio de Janeiro, the prevalence of gonorrhea was high at 9.5%. Of the 200 women surveyed, 8% were HIV-infected, confirming that the population studied had a high risk of STD exposure [16]. The prevalence of gonorrhea among 547 pregnant women attending a first-visit antenatal hospital clinic during 1999 and 2000 in Vila, Vanuatu, was 5.9%, but no women were found to be HIV-infected at that time [17]. The occurrence rates of gonorrhea were quite high among this population, reflecting the prevalence in the general population. A study in Thailand in 1996 that investigated the prevalence of STDs among pregnant women, where case reporting suggested a marked decrease in STDs after a campaign promoting condom use during commercial sex, showed that the prevalence of gonorrhea was extremely low at 0.2% [18]. By contrast, in a population in Nairobi, where condom use was advocated for commercial sex workers but not promoted to the same extent as in Thailand and not routinely practiced by the at-risk general population, in a cross-sectional study of 520 women seeking treatment at an STD clinic, 4% were infected with gonorrhea, and 29% were HIV-positive [19]. In Nigeria, where the prevalence of HIV infection is low, the rate of gonorrhea also is lower among pregnant women. In a cross-sectional study, 230 pregnant women attending the antenatal clinic of a teaching hospital in Nigeria from January 2000 to December 2000 were screened randomly to determine the prevalence of common STDs; 1.3% were found to have gonorrhea [20].

*N. gonorrhoeae* usually is transmitted from the infected maternal cervix during vaginal delivery. Ascending infection does occur, however, in the instance of prolonged rupture of the membranes and has been observed after cesarean delivery following ruptured membranes [21–24]. It has been estimated that colonization and infection of the neonate occur in only one third of instances in which the mother is infected [25]. The infant's mucous membranes become colonized on swallowing contaminated fluid during labor and delivery.

In instances of congenital infection, it is speculated that the chorioamnion is infected through an ascending infection [26]. Premature rupture of membranes then occurs, with early onset of labor and premature delivery or septic abortion [9,27–29]. This association was dramatically shown in one study in which premature rupture of membranes occurred in 6 (43%) of 14 women with untreated gonococcal infection during pregnancy compared with 4 (3%) of 144 women whose infection had been treated [29]. Screening and treatment programs for gonococcal infections during pregnancy are appropriate to reduce the risk of adverse pregnancy outcomes related to maternal infection.

## MICROBIOLOGY

*N. gonorrhoeae* is a gram-negative diplococcus. It uses glucose for growth, but not maltose, sucrose, or lactose. This is one of the characteristics used to distinguish *N. gonorrhoeae* isolates from *Neisseria meningitidis* and other colonizing *Neisseria* species, such as *Neisseria cinerea*, *Neisseria flava*, *Neisseria subflava*, *Neisseria lactamica*, *Neisseria mucosa*, and *Neisseria sicca*. *N. gonorrhoeae* produces acid only when grown in glucose. In addition, the organism is oxidase positive, hydroxyprolyl aminopeptidase positive, nitrate negative, DNase negative, catalase positive, strongly superoxol positive, and colistin resistant [30]. *N. gonorrhoeae* is an obligate aerobe, but lacks superoxide dismutase, which moderates the effects of oxygen radicals in most other aerobic bacteria. When grown in anaerobic conditions, virulent strains express a lipoprotein called Pan 1. Its function is unknown, but it elicits an IgM antibody response in acute infection.

When cultured in the laboratory, *N. gonorrhoeae* forms four different colony types. Pinpoint colonies, classified as type 1 and type 2, usually are seen only on primary isolation. These colony types are distinguished from the large granular colonies classified as type 3 and type 4 by the presence of pili, which are thin bacterial appendages on the cell surface that are involved in attachment to mammalian cells. *N. gonorrhoeae* has the genetic capacity to turn on and turn off the expression of pili [31]. With repeated subculturing at 37 ° C, the genes are no longer expressed, and the pili disappear, resulting in colonial-type changes, with type 1 colonies shifting to type 4 and type 2 colonies shifting to type 3. Associated with this change is a reduction in virulence [32]. *N. gonorrhoeae* also may form colonies that are either opaque or clear. This characteristic is related to the presence of a specific surface protein called outer membrane protein II. Transparent colonies lack outer membrane protein II and are more resistant to phagocytosis. Individual strains can also phase shift from forming opaque to forming clear colonies [33].

Colonial morphology is of no use in differentiating gonococcal types or strains. Strains can be differentiated by auxotyping. Different strains have differing stable auxotrophic requirements for amino acids, purines, pyrimidines, or vitamins. Typing based on these requirements has been useful in some epidemiologic surveys. Additionally, enzyme-linked immunosorbent typing, based on differences in protein I, can be done. Nine distinct strains are detectable with this typing system. It is clinically relevant in that type 1 and type 2 strains are more likely to disseminate in adult patients. Use of serologic typing schemes can detect three serogroups: WI, WII, and WIII. Strains 1 to 3 are usually found in serogroup WI, strains 4 to 8 are found in serogroup WII, and strain 9 is found in serogroup WIII [34]. Finally, strains also are typed by coagulation testing after exposure to monoclonal antibodies made against the outer membrane protein I. Two major serogroups exist: 1A, which has 26 subgroups, and 1B, which has 32 subgroups [35]. The combination of auxotyping and serologic typing is now used in most epidemiologic studies to determine the linkages among infected persons [36].

## PATHOGENESIS

To produce infection, *N. gonorrhoeae* first attaches to epithelial cells, penetrates into them, and then destroys the infected cells. Attachment to epithelial cells is related to the presence of pili and the outer membrane protein II [37]. Penetration of the gonococcus into cells occurs through either phagocytosis or endocytosis [38–40]. Several bacteria usually are found within each infected cell, but whether this represents invasion of the cell by multiple organisms or growth and multiplication of organisms within the infected cell is unknown. Gonococci possess a cytotoxic lipopolysaccharide and produce proteases, phospholipases, and elastases that ultimately destroy the infected cells. Some strains of gonococci seem to be relatively less susceptible to phagocytosis and are thought to be more capable of causing disseminated infection. Gonococci are found in the subepithelial connective tissue very quickly after infection. This dissemination may be due to the disruption of the integrity of the epidermal surface with cell death, or the gonococci may migrate into this area by moving between cells. Epithelial cell death triggers a vigorous inflammatory response, initially with neutrophils and then macrophages and lymphocytes in untreated patients.

Human serum contains IgM antibody directed against lipopolysaccharide antigens on the gonococcus, which inhibits invasion. An IgG antibody against a surface protein antigen also is normally present on some gonococci that are classified as serum-resistant gonococci; this antibody blocks the bactericidal action of the antilipopolysaccharide IgM antibody [41,42]. These serum-resistant strains are the most common ones involved in systemic infections in adults and probably in neonates as well [43]. Infants' sera, in which maternal IgM antibody is absent, do not show serum bactericidal activity against *N. gonorrhoeae* [44]; in theory, infants should be highly susceptible to invasive infection. Because such infection does not occur frequently, additional protective factors must function to prevent it.

*N. gonorrhoeae* produces an IgA1 protease, which inactivates secretory IgA by cleaving it at the hinge region. This inactivation facilitates mucosal colonization and probably plays a role in the poor mucosal protection seen against subsequent gonococcal reinfection. IgA1 protease is also a proinflammatory factor and can trigger the release of proinflammatory cytokines from human monocytic subpopulations and a dose-dependent T helper

type 1 T-cell response [45]. Although symptomatic gonococcal infection stimulates a brisk inflammatory response, it does not produce a significant immunologic response [46]. There is very little immunologic memory; as a result, recurrent infections occur easily on reexposure. Epidemiologic evidence suggests that at least partial protection is obtained against subsequent infection with the same serotype [47]. Generally, antibody responses are modest after initial infection, however, and no evidence of a boosting effect has been found when antibody levels are studied in response to subsequent infections. Also, adults with mucosal gonococcal infections have a discernible decreased $CD4^+$ count, which recovers with treatment or clearance of the infection.

It has been speculated that the gonococci actually have a suppressive effect on the host immune response. In support of this theory, *N. gonorrhoeae* Opa proteins more recently were shown to be able to bind CEACAM1 expressed by primary $CD4^+$ T lymphocytes and to suppress their activation and proliferation [48]. This immunosuppressive effect may have significant consequences in populations with coexisting epidemics of gonorrhea and HIV/AIDS. In a study of prostitutes in Nairobi, the presence of gonococcal cervicitis was shown to reduce interferon-γ production by HIV-1 epitope–specific $CD8^+$ T-lymphocyte populations, showing a deleterious effect of gonococcal cervicitis on HIV-1 immune control and susceptibility [49].

Because only approximately one third of neonates exposed to *N. gonorrhoeae* during vaginal delivery become colonized and infected, additional protective innate factors are in effect. Significant antibacterial polypeptide activity has been shown in human amniotic fluid and within the vernix caseosa [50,51]. The presence of numerous antibacterial polypeptides in the vernix may be important for surface defense against gonococcal infection, but specific studies have not yet been done.

Antibiotic resistance to penicillin, tetracycline, quinolones, and spectinomycin has become problematic in many regions [52]. Penicillin resistance can be a result of either alterations in the penicillin-binding protein or the production of penicillinase [53–55]. By 1991, 11% of all strains of *N. gonorrhoeae* in the United States were penicillinase-producing, and 32% of all strains were resistant to at least one antimicrobial agent. As a result, penicillin is no longer recommended for primary therapy for gonococcal disease in the United States and in other regions where these strains are commonly found.

## PATHOLOGY

In most affected infants, gonococcal disease manifests as infection of mucosal membranes. The eye is most frequently involved, but funisitis and infant vaginitis, rhinitis, and urethritis also have been observed [56–59]. Primary mucosal infection by *N. gonorrhoeae* involves the columnar and transitional epithelia. When pharyngeal colonization is looked for, it is found in 35% of ophthalmia neonatorum cases [60]. Systemic infection is rarely observed among neonates, but cases of meningitis and arthritis have been described [7,8,61–68]. Gonococcal scalp abscesses attributed to intrauterine fetal monitoring, omphalitis, and gingival abscess also have been reported [69–75]. One case of gonococcal ventriculitis has been reported in an infant who received a ventriculoamniotic shunt in utero [76].

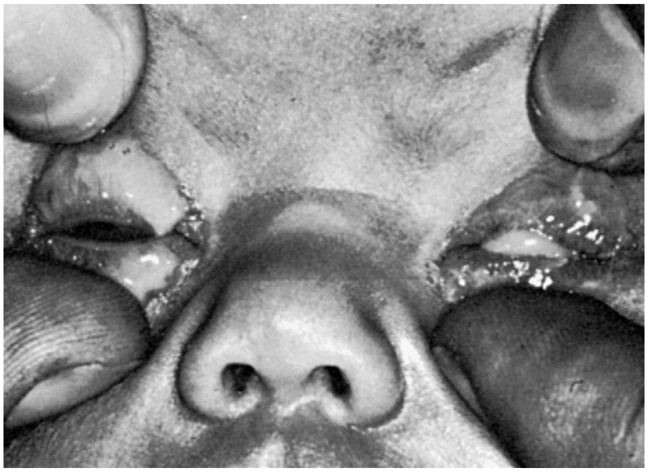

**FIGURE 15–1 Bilateral acute gonococcal ophthalmia neonatorum.** Appearance after inappropriate topical therapy for 2 weeks with neomycin–polymyxin B–bacitracin (Neosporin), sulfonamide, and chloramphenicol ophthalmic ointments.

## CLINICAL MANIFESTATIONS

Ophthalmia neonatorum caused by *N. gonorrhoeae* is classically an acute purulent conjunctivitis that appears 2 to 5 days after birth. Occasionally, the initial presentation is more subacute, or the onset may be delayed beyond 5 days of life [77,78]. Asymptomatic colonization has been documented [79]. Infants who become infected in utero may have symptoms at or shortly after birth [21,22,77]. Typically, early in the illness, tense edema of both lids develops, followed by profuse purulent conjunctival exudates (Fig. 15–1). If treatment is delayed, the infection progresses beyond the superficial epithelial layers of the eye to involve the subconjunctival connective tissue of the palpebral conjunctivae and the cornea. Infection of the cornea can lead to ulcerations, perforation, or rarely panophthalmitis. In some instances, it may result in loss of the eye [80]. Neonatal sepsis, arthritis, and skin abscesses caused by *N. gonorrhoeae* are not clinically distinguishable from conditions caused by other bacterial pathogens more commonly associated with these syndromes in this age group.

## DIAGNOSIS

Clinicians should suspect gonococcal ophthalmia neonatorum in an infant in whom purulent conjunctivitis develops during the first week of life or if what was thought to be chemical conjunctivitis is prolonged beyond 24 to 48 hours. Gram stain of the exudate usually reveals the gram-negative intracellular bean-shaped diplococci typical of *N. gonorrhoeae*, which provide a presumptive diagnosis. Other *Neisseria* species—in particular, *N. meningitidis*—cannot be distinguished from the gonococcus by Gram stain appearance. *N. gonorrhoeae* must be isolated and

tested for antibiotic susceptibility before a definitive diagnosis is made. A definitive diagnosis is important because of the public health and social consequences of the diagnosis of gonorrhea in an infant. If gonococcal ophthalmia neonatorum is suspected on the basis of the Gram stain appearance, cultures should be obtained from additional mucosal sites in the infant. The mother and her sexual partner or partners also should be tested for gonorrhea. Additional testing of the infant, mother, and sexual partners for other sexually transmitted infections, including HIV infection, is strongly recommended [81,82].

Isolation of *N. gonorrhoeae* from the exudate by culture is the diagnostic gold standard. Samples of the exudate should be collected by swabbing and should be inoculated directly onto blood agar, MacConkey's agar, and chocolate agar or chocolate-inhibitory media. The inhibitory medium should be placed in a commercial carbon dioxide incubator or candle jar to provide an adequate concentration of carbon dioxide and should be incubated at 36° C. Cultures are examined daily for the presence of typical colonies. Colonies resembling *N. gonorrhoeae* are identified further by Gram stain, by a positive oxidase test, and by use of glucose, but not maltose, sucrose, or lactose. Antibiotic sensitivity and penicillinase production should be tested.

Further testing to confirm the identification of the isolate may be done in a reference laboratory if desired. DNA-based and polymerase chain reaction–based technologies have replaced gonococcal cultures in many laboratories [81–85]. These assays have a high degree of sensitivity and detect more true cases of gonorrheal infection in adults than can be achieved by current culture methods. When correctly used, they also are very specific. Their suitability for diagnosis of gonorrheal infections in children without the additional use of culture methods, with the associated legal implications in older children, has not been extensively studied, however. Additionally, extensive use of these methods for primary diagnosis impairs the tracking of antimicrobial resistance patterns.

If gonococcal ophthalmia neonatorum is presumptively or definitively diagnosed, testing also should be conducted for other sexually transmitted pathogens, in particular, *Chlamydia trachomatis* because the two organisms frequently are found to coinfect pregnant women [86]. Also, the diagnosis of gonococccal infection in the neonate should trigger an investigation of the infant's mother and her sexual partner or partners for STDs.

## DIFFERENTIAL DIAGNOSIS

At the present time, *N. gonorrhoeae* causes less than 1% of cases of ophthalmia neonatorum in North America, western Europe, Australia, and New Zealand and in areas and communities elsewhere where there is access to prenatal care and STD prevention programs. In other areas, the risk of gonococcal ophthalmia is higher depending on the prevalence of gonococcal infection among the pregnant women in the population. Even in areas with high prevalence rates, however, ophthalmia caused by *N. gonorrhoeae* accounts for less than 5% of cases of neonatal conjunctivitis. Other organisms that can produce conjunctivitis in the newborn period and the relative overall frequency of resultant infections, the usual time of presentation since birth relative severity, and are shown in Table 15–2.

**TABLE 15–2** Differential Diagnosis of Ophthalmia Neonatorum

| Etiologic Condition/Agent | Percentage of Cases | Relative Severity | Usual Time of Onset after Delivery |
|---|---|---|---|
| Chemical conjunctivitis | Dependent on use | + | 6-24 hr |
| *Neisseria gonorrhoeae* | <1 | +++ | 2-5 days |
| *Neisseria meningitidis* | <1 | ++ | 2 days–2 wk |
| *Neisseria cinerea* | <1 | + | 2 days–2 wk |
| Herpes simplex virus | <1 | ++ | 2-14 days |
| *Chlamydia trachomatis* | 2-40 | + | 5 days–2 wk |
| Other bacteria | 30-50 | ++ | 2 days–2 wk |
| Group A and B streptococci | | | |
| *Staphylococcus aureus* | | | |
| *Haemophilus* species | | | |
| *Klebsiella pneumoniae* | | | |
| *Escherichia coli* | | | |
| *Pseudomonas aeruginosa* | | | |
| *Enterococcus* | | | |
| Pneumococcus | | | |

Generally, conjunctivitis seen within 24 hours of birth usually is assumed to be a reaction to silver nitrate, if this has been used for prophylaxis. As described previously, however, in the instance of prolonged rupture of membranes and premature delivery, symptomatic gonococcal ophthalmia may be observed during this period as well. Also, some infants have a less acute course, with appearance of symptoms after 5 days of age. Reliance on the timing between 2 and 5 days after delivery of the onset of symptoms may be an unreliable clinically distinguishing feature. The possibility of gonococcal infection should be considered in every neonate with conjunctivitis present after 24 hours of birth, and appropriate diagnostic testing to detect the organism should be done. In some instances, neonates with gonococcal ophthalmia neonatorum may be infected by additional pathogens, in particular, *C. trachomatis*. The differential diagnosis of cutaneous or systemic gonococcal infection of the neonate includes the bacterial or fungal pathogens that are frequently involved in these types of infections during this time period and are discussed in more detail in Chapters 6, 10, 33, and 34.

## TREATMENT

The principles of management of STDs in any age group apply when a neonate is determined to have a suspected or confirmed gonococcal infection. As stated previously, investigation and treatment of the mother and her sexual contacts for *N. gonorrhoeae* are essential, as is the investigation of the infant, the mother, and her sexual contacts for other sexually transmitted infections. STDs are like wolves—they travel in packs.

**TABLE 15–3** Recommended Treatment for Neonatal Gonococcal Infections

| Condition | Recommended Therapy |
|---|---|
| Ophthalmia neonatorum | Ceftriaxone 25-50 mg/kg IV or IM in a single dose, not to exceed 125 mg; topical antibiotic therapy alone is inadequate and is unnecessary if systemic treatment is administered |
| Gonococcal meningitis, arthritis, or scalp lesions | Ceftriaxone 25-50 mg/kg/day IV or IM in a single daily dose for 7 days *or* cefotaxime 25 mg/kg IV or IM every 12 hours for 7 days, with a duration of 10-14 days if meningitis is documented or 14 days if arthritis is documented |
| Known exposure at birth but asymptomatic | Ceftriaxone 25-50 mg/kg IV or IM in a single dose, not to exceed 125 mg |

*IM, intramuscularly; IV, intravenously.*

As discussed previously, because a significant proportion of gonococci worldwide is resistant to penicillin, either by decreased penicillin binding or by penicillinase production, this antibiotic is no longer recommended for therapy, unless the infecting isolate has been tested and found to be sensitive. Most recommendations and guidelines for the treatment of gonococcal ophthalmia neonatorum identify ceftriaxone as the agent of choice (Table 15–3) [81,82]. Regimens using this drug have been studied and shown to be effective [87–89]. Kanamycin is an alternative, but is not as effective, with a failure rate of approximately 5% [90]. Ceftriaxone should be administered cautiously to infants with hyperbilirubinemia, especially infants born prematurely. Infants who have gonococcal ophthalmia should be hospitalized and evaluated for signs of disseminated infection (e.g., sepsis, arthritis, meningitis). One dose of ceftriaxone is adequate therapy for gonococcal conjunctivitis. Disseminated infection in the neonate should be treated in consultation with an expert in infectious diseases. Infants born to mothers who have documented untreated infection are at high risk of acquiring *N. gonorrhoeae*. If the membranes have been ruptured, if the infant is premature, or if close follow-up cannot be ensured, treatment for ophthalmia neonatorum, rather than use of eye prophylaxis, is recommended.

## PROGNOSIS

With early recognition and appropriate treatment, cure rates for gonococcal ophthalmia and other neonatal manifestations of gonococcal infection in the newborn are close to 100%. By contrast, permanent corneal damage after gonococcal ophthalmia neonatorum was the usual clinical outcome in the preantibiotic era.

## PREVENTION

Prevention of gonococcal infection of the fetus and neonate is best done by preventing gonococcal infection of the mother. One way to accomplish this goal is by the reduction of the prevalence of *N. gonorrhoeae* in the core high-risk populations that serve as its reservoir for pregnant women. Targeted treatment and prevention campaigns among commercial sex workers, sexually active adolescents and young adults who have multiple partners, and groups with other risk factors that result in increased high-risk sexual activity such as individuals with street drug and alcohol abuse problems and homosexual men who have multiple contacts would reduce the prevalence in the general population. Education of youth before sexual maturity about the risks of STDs and about ways in which they can protect themselves from acquiring these diseases does not increase the rates of sexual activity among adolescents and should be encouraged as a joint responsibility of parents or primary care providers and the schools. Provision of accessible health care with readily available antibiotics that are appropriate and effective against circulating strains of *N. gonorrhoeae* also is imperative for this purpose. Finally, to support optimal health behaviors, persons of all ages need to be able to feel confident that they will not be stigmatized for seeking health care for an STD.

Because infection with *N. gonorrhoeae* during pregnancy may result in adverse pregnancy outcomes, such as premature rupture of membranes and preterm delivery, screening of pregnant women for infection in early pregnancy is advisable. Women identified as having gonococcal infection should receive prompt treatment [81,82]. Recommended treatment includes the use of cefixime, 400 mg orally, in a single dose if available, or ceftriaxone, 125 mg intramuscularly in a single dose. Women for whom a third-generation cephalosporin is contraindicated should receive spectinomycin, 2 g intramuscularly as a single dose. Either erythromycin or amoxicillin is recommended for treatment of presumptive or diagnosed coinfection with *C. trachomatis*. Follow-up cultures to ensure eradication of the infection are imperative.

Testing for other STDs should be done, and the mother should be offered HIV testing. In addition, counseling related to avoidance of further infection is an important component of management. Tracing and treatment of sexual contacts are necessary to reduce the risk of subsequent infection. In one study in Louisiana of 751 pregnant women whose charts were reviewed retrospectively, 5.1% were diagnosed with gonorrhea at the first prenatal visit, and 2.5% acquired the infection during their pregnancy [91]. Women whose sexual behavior or social circumstances place them at risk of acquiring sexually transmitted infection during pregnancy should be retested for gonorrhea (and other STDs) in the third trimester. Retesting is most conveniently done at the time of screening for group B streptococci.

Since the late 1800s, eye prophylaxis has been the hallmark of prevention of gonococcal ophthalmia neonatorum. Currently, many jurisdictions mandate the use of ocular prophylaxis for newborns through legislation. Most others recommend and encourage its use. The issue is controversial in areas of low prevalence of *N. gonorrhoeae* infection and among populations with extremely low risk of the disease. In these situations, the concerns regarding the complications of the use of the prophylactic agents must be balanced against the actual risk of the disease and the ability, or the wish, to provide an alternative

management approach involving close observation of the infant with early therapy if necessary.

At the present time, data from clinical trials support the use of 1% silver nitrate, 0.5% erythromycin, 1% tetracycline, or 2.5% povidone-iodine for prophylaxis against gonococcal ophthalmia neonatorum [4–6,81,82,92–96]. All of these agents are less effective against chlamydial conjunctivitis, however, and to date, there is no truly effective ocular agent to prevent this infection. Most agents are well tolerated, although a chemical conjunctivitis commonly is seen after instillation of silver nitrate. This reaction involves epithelial desquamation and a polymorphonuclear leukocytic exudate [97] and usually appears within 6 to 8 hours and disappears within 24 to 48 hours. A mild chemical conjunctivitis may be seen in 10% to 20% of infants who received povidone-iodine prophylaxis as well. Use of antibiotic agents has the potential to lead to increased antibiotic resistance in other colonizing bacteria, which could lead to outbreaks of infection in the nursery [98].

Failure of prophylaxis can occur. If the illness is established by the time of delivery, ocular prophylaxis is ineffective. Irrigation of the eyes with saline too soon after the application of silver nitrate has been suggested by some experts to be the cause of such failure. In extremely rare instances, infection may be acquired after prophylaxis had been provided. Occasionally, the erythromycin eye ointment may not have penetrated to the eye itself as a result of difficulties in keeping the infant's eye exposed during application of the ointment.

At the present time, specific prophylaxis given immediately (minimum delay of 1 hour) after birth, using any of the following regimens, is recommended by most professional societies and government bodies: (1) 1% silver nitrate in single-dose ampules, (2) 0.5% erythromycin ophthalmic ointment in single-use tubes, or (3) 1% tetracycline ophthalmic ointment in single-use tubes. Povidone-iodine also is a safe and effective alternative in resource-poor countries.

CHAPTER

16

# SYPHILIS

Tobias R. Kollmann ⚙ Simon Dobson

## CHAPTER OUTLINE

Syphilis is a sexually transmitted disease caused by infection with the bacterium *Treponema pallidum*. Congenital syphilis results when the infection is transmitted from a pregnant mother to her fetus. Although some evidence suggests syphilis was present in Africa and China centuries earlier, the first European epidemic coincided with the return of Columbus from the New World in 1493. It was speculated that Columbus' crew might have contracted the "serpentine disease of Hispaniola" from the island where Haiti and the Dominican Republic are situated today. Another theory is that syphilis entered into a susceptible European population around that time from endemic yaws or bejel of African peoples [1]. Regardless of its origins, syphilis affected Europeans over many centuries, rapidly sweeping through the continent. The first major publication on syphilis was written by Francisco Lopez de Villalobos and appeared in 1498 [2,3]. In 1530, Hieronymus Fracastorius wrote a poem describing an Italian shepherd boy named Syphilus, who contracted the "French disease" sweeping through Europe in the early 16th century [4]. A generation later, Gale introduced the word *syphilis* into the English language [5]. The subsequent spread of syphilis throughout the rest of the world was facilitated largely by wars with associated large troop and population movements and general social disarray [6,7].

The venereal transmission of syphilis was not recognized until the 18th century [1]. Delineation of the characteristics of syphilis was hindered further by the confusion of its symptoms with symptoms of gonorrhea: In 1767, John Hunter, an English experimental biologist and physician, inoculated himself with urethral exudate from a patient with gonorrhea. The patient also had syphilis, however, and the subsequent symptoms experienced by Hunter convinced two generations of physicians of the unity of gonorrhea and syphilis. The separate nature of gonorrhea and syphilis was shown in 1838 by Ricord, who reported his observations on more than 2500 human inoculations. Recognition of the stages of syphilis followed, and in 1905, Schaudinn and Hoffman discovered the causative agent. The following year, Wassermann introduced the diagnostic blood test that bears his name [1].

Lopez and Fracastorius had already mentioned syphilis of the newborn, but they and others thought that infants became infected through contact at delivery or postpartum by ingestion of infected breast milk [2,5,8]. Because many mothers of infants with congenital syphilis had no obvious signs of infection, some investigators believed that congenital disease was transmitted by the father [1]. A lengthy account of the signs of syphilis in infants was published in 1854 by Diday [5], but he failed to recognize

DOI: 10.1016/B978-1-4160-6400-8.00016-X

that infants who were without symptoms by 6 months of age could still have been infected at or before birth. In 1858, Sir Jonathan Hutchinson described the famous triad of late congenital syphilis: notched incisor teeth, interstitial keratitis, and eighth cranial nerve deafness [9]. Myriad further presenting signs and symptoms have earned syphilis the title of "the great imitator" [10,11].

The horror syphilis causes is best encapsulated in its other old name *lues*, which means "plague" in Latin. This is still the most appropriate name because a staggering number of adults and newborn infants in developed and developing countries are suffering and dying as a consequence of infection with *T. pallidum*. The most shocking aspect of this plague is that hundreds of thousands are newly infected every year despite the availability of feasible, cost-effective interventions to detect, treat, and prevent syphilis [12,13]. The World Health Organization (WHO) estimates that globally every year 1 million pregnancies are complicated by syphilis, with approximately half resulting in early abortion or perinatal death, a quarter resulting in infants with low birth weight or premature birth, and a final quarter resulting in infants with overt congenital syphilis [13]. The 2000 Report on Global Burden of Disease estimated that congenital syphilis is responsible for 1.3% of deaths among live-born children younger than 5 years [14]. The annual number of children born with congenital syphilis has now exceeded the number of newborns with human immunodeficiency virus (HIV) [12,15]. Consequently, the elimination of congenital syphilis is an important global objective [12,15,16].

## ORGANISM

Syphilis is caused by *T. pallidum*. The name *Treponema* (Greek, meaning "turning thread") is based on its twisting motion, and *pallidum* (Latin) is derived from its pale, yellow color. *T. pallidum* belongs to the order Spirochaetales, family Spirochaetaceae, and genus *Treponema*. *Borrelia*, *Spirochaeta*, *Leptospira*, and *Cristispira* are other genera of this order, grouped together primarily based on their morphologic characteristics (i.e., helix-shaped) (Fig. 16–1). *T. pallidum* has approximately 8 to 14 helices per cell [17]. Despite greater than 95% sequence homology, complete DNA sequencing has allowed the human disease–causing *Treponema* to be identified as subspecies—*T. pallidum* subspecies *pallidum* (syphilis), *T. pallidum* subspecies *pertenue* (yaws), *Treponema* subspecies *carateum* (pinta), and *T. pallidum* subspecies *endemicum* (Bejel) [18–23]. Only *T. pallidum* and possibly *T. pertenue* [24] can cause congenital infection [25–27]. Several nonpathogenic treponemes also inhabit the oral cavity and intestinal tract of humans [28]. *T. pallidum* has finely tapered ends, lacking the hook shape found in several human commensal spirochetes [18,19]. An outer membrane consisting of a lipid bilayer surrounds the endoflagella, cytoplasmic membrane, and protoplasmic cylinder. The spirochete's corkscrew motility results from the action of these endoflagella and can be observed in fresh preparations examined with the dark-field microscope [29–32].

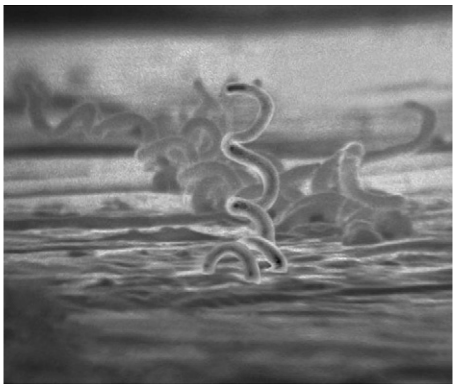

**FIGURE 16–1** Electron micrograph of *Treponema pallidum* on cultures of cotton-tail rabbit epithelium cells, displaying the characteristic helical structure of treponemes. *(Courtesy of CDC/Dr. David Cox; Public Health Image Library #1977.)*

The genome of *T. pallidum* subspecies *pallidum* (Nichols strain; maintained in rabbits since 1912) has been sequenced in its entire length. It represents an approximately 1-Mb circular chromosome with slightly more than 1000 predicted open reading frames (ORFs) encoding all factors necessary for replication, transcription, translation, and mobility, but only a minimal number of genes encoding molecules important in metabolism, indicating a necessary close interaction with the host cell [23,33–36]. In contrast to many bacterial pathogens, *T. pallidum* does not seem to rely on iron acquisition from the host [34,36,37]. Biologic functions have so far been predicted for only about 55% of *T. pallidum* ORFs, and a further 17% show homology with proteins from other species; a high proportion of *T. pallidum* ORFs are still uncharacterized and presumably contribute to its distinctive and complex parasitic strategy, including immune evasion, latency, and a feature unique to *T. pallidum* subspecies *pallidum*—neuroinvasion. The genome sequence contains ORFs encoding for putative virulence factors similar to known bacterial hemolysins and cytotoxins, but does not seem to have the mechanism for secreting them into the host. Genetic polymorphisms more recently identified at two loci have enabled strain typing of clinical isolates of *T. pallidum*, providing new tools for the investigation of syphilis transmission and epidemiology [10,38].

*T. pallidum* is a macroaerophilic gram-negative bacterium that depends primarily on glycolysis for energy production. It is highly sensitive to oxygen and temperature and is not readily maintained in culture [26,39–41]. It can be passaged for a limited number of replicative cycles with a generation time of 30 to 33 hours using rabbit epithelial cell monolayers under microaerobic conditions at 33° C to 35° C [10]. *T. pallidum* can be propagated by intratesticular inoculation of rabbits, where it displays a slow replicative cycle of approximately 30 hours. From infected rabbit testes, *T. pallidum* can be purified through density centrifugation. Such purified organisms retain their antigenicity, but not their motility or their virulence. Outside of humans, only rabbits and primates infected with *T. pallidum* develop primary and secondary, but not tertiary, syphilis, and neither rabbits nor primates have been shown to pass *T. pallidum* on vertically [25,42,43]. Although *T. pallidum* can be passed on vertically in pigs, no good animal model for congenital syphilis exists that

recapitulates the clinical findings in humans transplacentally infected [44–47]. This lack of a good animal model and the inability to culture and manipulate these organisms in vitro have prevented a detailed mechanistic understanding of virulence mechanisms or host-pathogen interactions in congenital syphilis [48,49].

# TRANSMISSION

Syphilis can be passed horizontally from person to person through direct contact, such as during sexual activity resulting in acquired syphilis, or vertically from mother to infant, resulting in congenital syphilis. The organism does not survive outside of its human host and is easily killed by heat, drying, soap, and water. Syphilis is not known to be spread through casual contact or through contact with fomites [50].

## ACQUIRED SYPHILIS

Humans are the only known natural host of *T. pallidum*. Horizontal transmission results primarily from sexual activity, although anecdotal reports cite kissing as a potential route as well [51]. Because of the low survival rate of *T. pallidum* outside of its host, direct contact with an infected person's bodily secretions containing spirochetes is necessary for transmission. Although sexual transmission depends on many factors, such as stage of the disease, overall around half of individuals who have sexual contact with an infected partner acquire the disease, with an estimated median infective dose of 50 bacteria [52–54]. Because sexual contact is the most common mode of transmission for acquired disease, the sites of inoculation usually are the genital organs, but lips, tongue, and abraded areas of the skin have been described as well. Such an entry point is identified as the site of the initial ulcerating sore, or chancre [51]. Health care providers or laboratory workers have apparently become infected with *T. pallidum* through accidental contact with infected secretions, when appropriate protection gear (gloves) was not worn [51].

## CONGENITAL SYPHILIS

Vertical transmission from infected mother to child most often occurs prenatally, but perinatal and postnatal transmission have been described. Although transmission of syphilis to the fetus can occur throughout pregnancy (spirochetes have been visualized in tissue at gestational age of 9 weeks) [55–57], the likelihood of vertical transmission increases with advancing gestation. The organism is isolated with increasing frequency during gestation from umbilical cord blood, amniotic fluid [58–62], and placenta [63–65]. A newborn occasionally may be infected perinatally (i.e., at delivery by contact with an infectious lesion present in the birth canal or perineum). Postnatal transmission from mother to child is exceedingly rare. Centuries ago, when it was more common for infants to be fed by a wet nurse, small epidemics of syphilis were caused by an infectious lesion on the nipple of a wet nurse, but no data indicate that breast milk itself is associated with mother-to-child transmission [66,67].

The likelihood of vertical transmission is directly related to the maternal stage of syphilis, with early primary syphilis resulting in significantly higher transmission rates than late latent infection (known as Kassowitz's law) [68,69]. This transmission pattern may relate to maternal spirochetemia in early syphilis [70]. Among women with untreated primary or secondary early syphilis, the rate of transmission is 60% to 100% and slowly decreases with later stages of maternal infection to approximately 40% with early latent infection and 8% with late latent infection. In one study, in which *T. pallidum* was passed on from mother to fetus during early primary or secondary (<4 years' duration) untreated syphilis, approximately half of the infants were born prematurely, stillborn, or died as neonates, and congenital syphilis developed in the other half (i.e., 100% were affected). In contrast, in women with early latent syphilis, 20% to 60% of their infants were healthy at birth, 20% were premature, and only 16% were stillborn; 4% died as neonates, and 40% of infants appearing healthy at birth developed the stigmata of congenital syphilis later in life. In the case of untreated late syphilis, about 70% of newborns appeared healthy, 10% were stillborn, and approximately 9% were premature; about 1% died as neonates, and about 10% of infants appearing healthy at birth developed signs of congenital syphilis later in life [68,69,71]. A family study illustrating Kassowitz's law described a syphilitic mother who had five pregnancies resulting in eight children: [72] The first pregnancy produced a stillborn infant; the second produced a full-term infant with congenital syphilis; the third produced triplets, two of whom had congenital syphilis; the fourth produced twins, one of whom had congenital syphilis; and the fifth produced a healthy full-term infant.

## SYPHILIS AND HUMAN IMMUNODEFICIENCY VIRUS

Despite the recognition that syphilis and HIV are a dangerous combination, limited conclusive data exist to describe the interaction between the two infections or their impact on vertical transmission [73,74]. Potential interactions include acceleration of the natural history of either disease, alterations in the clinical or laboratory manifestations, increased risk for syphilitic complications, and diminished response to syphilis therapy [10,51,75,76]. Genital sores (i.e., chancres) caused by syphilis make it easier to transmit sexually and acquire HIV infection, with an estimated twofold to fivefold increased risk of acquiring HIV if exposed to that infection when a syphilitic chancre is present [50]. This increased risk is likely caused by the breaks in the skin or mucous membranes in a syphilitic chancre, which bleed easily and, when they come into contact with oral, genital, and rectal mucosa, increase the infectiousness of and susceptibility to HIV.

Virulent *T. pallidum* can promote the induction of HIV gene expression in infected cells, possibly resulting in increased systemic HIV levels and more rapid progression of HIV infection [77]. Increasing proportions of newborns with congenital syphilis also are born to mothers with HIV, and vice versa. One study noted higher rates of congenital syphilis in infants born to

coinfected mothers, but the diagnosis of congenital syphilis was based on the older surveillance definition used by the U.S. Centers for Disease Control and Prevention (CDC) [78] and not on strict diagnostic criteria [79]. Immune dysfunction associated with HIV infection may also permit a greater degree of treponemal proliferation and lead to a higher rate of fetal infection. HIV-infected women who acquire syphilis during pregnancy also may not respond adequately to currently recommended penicillin therapy, increasing the risk of fetal infection with *T. pallidum* [80]. Available data suggest, however, that if the natural history of acquired syphilis is modified by HIV, the difference shows considerable overlap with the course of syphilitic disease progression in persons without HIV [10].

## SYPHILIS IN SEXUALLY ABUSED CHILDREN

Identification of syphilis in young children raises the question of possible sexual abuse [81]. It is an uncommon complication among sexually abused children, found in 1% or less in a case series from the United States. The frequency of syphilis transmission to sexually abused children may be higher, however, in regions with higher adult prevalence of the disease. The clinical manifestations may provide insight into the timing of acquisition of infection. This information may not always help to resolve the potential dilemma of whether the clinical findings are those of previously unrecognized congenital syphilis versus postnatally acquired syphilis. Also, some experts have postulated that antibiotics commonly prescribed for common childhood illnesses may partially treat congenital syphilis and alter the nature of late clinical manifestations. Evaluation of children by specialists in the area of child sexual abuse is recommended. Children diagnosed with syphilis also should be evaluated for HIV infection and other sexually transmitted diseases as clinically indicated.

## INFECTION CONTROL

Standard precautions are recommended for all patients, including infants with suspected or proven congenital syphilis. Infected infants and adults with infectious lesions should be placed in contact isolation for the first 24 hours of therapy, and appropriate protective gear (e.g., gloves) should be worn by staff members for all patient contact during this period. When antimicrobial therapy has been initiated, the risk of transmission is virtually nonexistent because penicillin in sufficient dosage causes a complete disappearance of viable treponemes from syphilitic lesions within a few hours [82]. All people, including hospital personnel, who have had unprotected close contact with a patient with early congenital syphilis before identification of the disease or within the first 24 hours of therapy should be examined clinically for the presence of lesions 2 to 3 weeks after contact. Close unprotected contact is defined as skin (intact or abraded) contact with infectious bodily fluids. Serology in the exposed individual should be assessed at time 0 and again at 1 month and 3 to 6 months postexposure, or sooner if symptoms occur. If the degree of exposure is considered substantial, immediate treatment should be considered, as outlined subsequently under postexposure prophylaxis in "Therapy." [81,83]. All exposures should also be reported to the occupational health office.

# EPIDEMIOLOGY

The epidemiologic curve of syphilis has consistently reflected social trends, with an upward swing during stressful societal transitions [84]. After major public health successes in the early 1990s, the incidence of acquired syphilis showed an alarming resurgence throughout the world. The trends for congenital syphilis follow trends of acquired syphilis in women.

## ACQUIRED SYPHILIS

Because of the exquisite susceptibility of *T. pallidum* to penicillin, it was believed that use of this antimicrobial agent would lead to the virtual disappearance of acquired syphilis. A dramatic decline in the number of cases did occur after the introduction of penicillin, with the incidence reaching a low point in the United States in the mid-1950s. When a disease approaches eradication, however, often the control program rather than the disease is eradicated. As a result of reduction in funds in the early 1960s, syphilis resurged. More resources were again committed to control efforts, and the incidence of syphilis promptly declined in the 1970s, only to increase dramatically again in the 1980s [85,86]. The impact of illegal drugs, particularly crack cocaine, seems to have played a major role in that resurgence [85–88], but a reduction in resources for syphilis control programs can be implicated as well [85,89].

Secondary to increased funding and focus on public health intervention, from 1990–2000, the incidence of primary and secondary syphilis in the United States decreased by 90% [50,85,90–92]. The reasons for this dramatic success were many, but likely include the following: (1) wider screening practices secondary to medical and public awareness of the syphilis epidemic of the late 1980s, which led to identification and treatment of infected individuals; (2) increased state and local funding for syphilis control programs such as partner notification, community-based screening and presumptive treatment strategies, and risk reduction counseling; (3) introduction of HIV prevention programs that target prevention of other sexually transmitted diseases; (4) decrease in crack cocaine use and sex-for-drug behaviors; and possibly (5) development of acquired immunity to syphilis among high-risk populations, which may have resulted in less reacquisition of infectious syphilis. These trends did not continue, and the upward swing is becoming evident once more (Fig. 16–2).

In the United States in 2005–2006, the total number of cases of syphilis (all stages—primary and secondary, early latent, late, late latent, and congenital syphilis) increased 11% (from 33,288 to 36,935). The rate of primary and secondary syphilis in 2006 (3.3 cases per 100,000 population) was 13.8% higher than the rate in 2005—far greater than the Healthy People 2010 target of 0.2 cases per 100,000 population. The rate increased in all racial and ethnic groups (5.6% among non-Hispanic whites

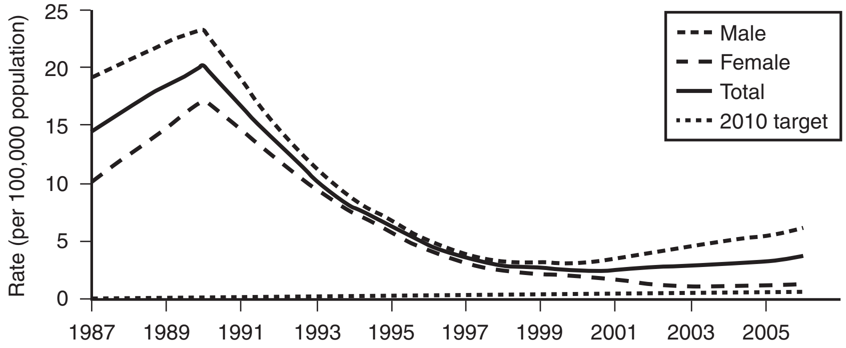

**FIGURE 16–2 Primary and secondary syphilis rates, total and by sex, United States, 1987–2006, and the Healthy People 2010 target.** The Healthy People 2010 target for primary and secondary syphilis is 0.2 case per 100,000 population. *(From Division of STD Prevention. National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention. Last updated November 13, 2007. Available at http://cdc.gov/std/stats/figures/figure27.htm.)*

[from 1.8 to 1.9 cases per 100,000 population], 16.5% among African Americans [from 9.7 to 11.3 cases per 100,000 population], 12.5% among Hispanics [from 3.2 to 3.6 cases per 100,000 population], 18.2% among Asian/Pacific Islanders [from 1.1 to 1.3 cases per 100,000 population], and 37.5% among American Indian/Alaska Natives [from 2.4 to 3.3 cases per 100,000 population]). Most primary and secondary syphilis cases occurred in persons 20 to 39 years old; rates were highest in women 20 to 24 years old and in men 35 to 39 years old. Rates have increased in men each year from 2000–2006 from 2.6 to 5.7, with 65% of cases in 2006 occurring among men who have sex with men (it is only since 2005 that the CDC requested that all state health departments report gender of sex partners for persons with syphilis). After persistent declines since 1990, the rate of primary and secondary syphilis among women increased from 0.8 case per 100,000 population in 2004 to 0.9 case per 100,000 population in 2005 to 1 case per 100,000 population in 2006 [85].

Similar trends have been observed in Canada. Just when Canadian public health officials aimed at possibly eliminating syphilis entirely, Alberta and British Columbia reported outbreaks of syphilis: From 1996–1999, the rate of infectious syphilis in British Columbia increased from 0.5 to 7.7 cases per 100,000 population, with incidence peaks of 150 cases per 100,000 among sex trade workers and their clients [93–95].

Local outbreaks of primary and secondary syphilis have occurred in North America in almost cyclic patterns roughly every 7 to 10 years [96–98]. These cycles underscore the need for syphilis elimination rather than merely control. The idea for a comprehensive approach to eliminate endemic syphilis in the United States had been raised several years back, with the CDC [78] developing a National Plan for Elimination of Syphilis from the United States [50,85]. The plan did not succeed, however, and had to be revised in 2006 in the face of resurgent rates [85].

## CONGENITAL SYPHILIS

The incidence of congenital syphilis closely mimics the incidence of primary and secondary disease in women of childbearing age: The incidence of congenital syphilis increased dramatically in the late 1980s, then declined, but again has increased after 2005. The dramatic increase in the number of cases of congenital syphilis in 1990–1991 was due to an increase in actual cases and to the use of revised reporting guidelines beginning in 1989 [96,99,100]. Previous criteria for reporting cases of congenital syphilis had been based on a clinical case definition [101]. Because of the high incidence of congenital disease in infants born to inadequately treated mothers, current definitions of congenital syphilis for a probable case (which should be reported and treated) require only (1) that the infant be born to a mother with untreated or inadequately treated syphilis or (2) that the infant has physical or laboratory signs of congenital syphilis. Use of these guidelines increased the number of reported cases of congenital syphilis almost fourfold in the 1990s [102,103].

The current definition by the CDC acknowledges the public health burden of the disease because these infants require medical and public health interventions. Using this new surveillance-based case definition, up until 2005, the rate of congenital syphilis in the United States had declined every year over 14 consecutive years, with an overall reduction of 74.2%. From 2005–2006 for the first time, the rate of congenital syphilis increased again (3.7%, from 8.2 to 8.5 cases per 100,000 live births). In 2006, 349 cases were reported in the United States compared with 339 cases in 2005. In 2006, 26 states, the District of Columbia, and one outlying area had rates of congenital syphilis that exceeded the Healthy People 2010 target of 1 case per 100,000 live births [85], indicating how widespread the resurgence of congenital syphilis is in the United States. In Canada, the rates of congenital syphilis followed a similar trend [104]. Delayed access to prenatal care has been identified as the main issue, and nearly all mothers in the outbreak in downtown Vancouver who delivered an infant with congenital syphilis had histories of substance abuse or street involvement [84].

## GLOBAL PERSPECTIVE

Worldwide, syphilis has grown into a staggering public health problem. According to a WHO estimate, 12 million people are infected with syphilis each year, and 90% of these infections occur in developing countries [105]. In Europe, the emerging resurgence has brought about great concern. In the United Kingdom, the highest number of congenital syphilis cases in 10 years were identified in 2005 [106], raising doubts that existing antenatal programs are adequate for the identification and treatment of women at risk [11,107]. Outbreaks have also been

registered in Ireland, France, Holland, Norway, Germany, and Switzerland [108–110]. Congenital syphilis was very rare before 1990 in Eastern Europe and the former Soviet Union, but the number of infants born with syphilis in the Russian Federation increased from 29 in 1991 to 743 in 1999, an increase from 0.9 to 8.5 cases per 100,000 live births. Overall, 1% to 2% of all pregnancies in Russia and other countries of the former Soviet Union now occur in women with syphilis.

In sub-Saharan Africa, syphilis is common among women of childbearing age, with more recent national surveys reporting rates of 3.1% in Uganda, 4.2% in Madagascar, 6.6% in Ghana, and 8.3% in Zambia [111,112]. In Burkina Faso, 2.5% of all pregnancies occur in women with syphilis, and in Cameroon, 17.4% of pregnancies occur in women with syphilis. In southern Africa, an estimated 25% of all stillbirths and 10% of all neonatal deaths are due to congenital syphilis [113]. In South America, the problem of syphilis and congenital syphilis is recognized as well. In Buenos Aires, 10% of women with reactive serologic tests for syphilis had a history of stillbirth that was believed to be caused by syphilis. In Bolivia, 26% of women who were delivered of stillborn infants had syphilis compared with only 4% of mothers of live-born infants [114]. The highest documented increase in acquired and congenital syphilis has been noted in China, where congenital syphilis has had an average yearly increase of 71.9%, from 0.01 cases per 100,000 live births in 1991 to 19.68 cases in 2005 [115]. These statistics likely still underestimate the total burden of congenital syphilis in China because they do not take into account stillbirths.

More recent data from the WHO indicate that only 68% of women in the world currently receive antenatal care. Even if perfectly executed, existing prenatal programs would not be able to prevent transmission of syphilis in the one third of pregnant women not seen early enough to be tested and treated [116]. The global toll of congenital syphilis is severe: Every year, about 1 million pregnancies globally are adversely affected by syphilis (about 270,000 infants are born with congenital syphilis, 460,000 pregnancies end in abortion or perinatal death, and 270,000 infants are born prematurely or with low birth weight). This represents a higher impact than any other major neonatal infection, including HIV infection and tetanus [117,118]. With that, considerable burden is placed on the already limited health services in many developing countries [119,120]. Newborns with congenital syphilis are more likely to be admitted to a neonatal intensive care unit, to stay longer in the hospital, and to receive care costing three times more than newborns without the disease. In one large South African referral hospital, on average 1 neonatal intensive care unit bed out of a total of 12 is occupied by an infant with syphilis [15]. In most countries, more attention has been given to screening for HIV, for which, at present, no cure is available; this has led to the situation where infants are "avoiding HIV but dying of syphilis" [16].

## PATHOGENESIS

In an infected pregnant woman, the parasite encounters a host environment that is altered to favor the development of the fetus [10]. Understanding the pathogenesis of *T. pallidum* in pregnancy relies on understanding the complex relationships between the unique ability of this particular treponeme to cross the placental barrier and its ability to cause fetal demise or the many early and late manifestations of congenital syphilis in a live-born infant. These complex and changing relationships are superimposed on the genetic background of the mother and the fetus, which together govern the host response to infection during the different stages of pregnancy and development [10]. The complexity of these host-pathogen relationships has made gathering mechanistic insights into the molecular, cellular, and organism pathogenesis extremely difficult.

## TREPONEMAL VIRULENCE–ASSOCIATED FACTORS

As reviewed by Woods [121], congenital syphilis starts with *T. pallidum* bacteria crossing from mother to fetus. Transplacental transmission during maternal spirochetemia can occur at 9 to 10 weeks of gestation and at any subsequent time during pregnancy. Viable spirochetes in amniotic fluid obtained by amniocentesis from a woman with early syphilis have been reported at 14 weeks of gestation, proving that the fetus can sustain replication of viable treponemes after infection with *T. pallidum* very early in pregnancy [60]. Transmission in utero causes the wide dissemination of the organism in the fetus (analogous to secondary acquired syphilis). Untreated congenital syphilis can progress through the same stages as postnatally acquired syphilis. Infection begins when virulent *T. pallidum* attach to host cells via the proximal hook. A ligand-receptor adherence mechanism involving the treponemal outer membrane proteins seems to be present. Virulent strains attach to metabolically active mammalian cells, and treponemes are capable of multiplication only during attachment. Highly replicative fetal and infant cells seem to support treponemal growth maximally, and endothelial cells seem to be the prime target. Virulent treponemal strains produce hyaluronidase, which may facilitate the perivascular infiltration that is apparent by histopathologic study. Virulent *T. pallidum* is coated with fibronectin of host origin. This coating seems to protect the organism from antibody-mediated phagocytosis; allows the organism to adhere to the surface of host phagocytes with only limited ingestion; may block complement-mediated lysis of the coated treponemes; and, finally, may allow the treponemes to acquire host proteins, such as ceruloplasmin and transferrin, on which they are dependent [121,122].

## HOST RESPONSE

Pathologic changes in congenital syphilis are similar to changes that occur in acquired syphilis except for the absence of a primary or chancre stage. Because infection involves the placenta [55] and spreads hematogenously to the fetus, widespread involvement is characteristic. No matter which organ is involved, the essential microscopic appearance of lesions is that of perivascular infiltration of lymphocytes, plasma cells, and histiocytes, with obliterative endarteritis and extensive fibrosis [25,123]. These typical histopathologic features of the inflammatory response to

invasion by *T. pallidum* suggest an important role for immune-mediated injury in the pathogenesis of congenital syphilis [124]. Harter and Benirschke [125] showed spirochetes in fetal tissue from spontaneous abortions at 9 and 10 weeks of gestation. The apparent lack of pathologic changes in fetal tissues earlier than the 5th month of gestation could be a result of lower fetal immune function during early gestation [57].

*T. pallidum* infection simultaneously elicits local and systemic innate and adaptive immune responses [126,127]. It is generally believed that a strong T helper type 1 ($T_H1$) response to any infection during pregnancy may compromise pregnancy outcome. In pregnancy, a gradual dampening of the intensity of the innate and cell-mediated immune responses to favor the maintenance and growth of the fetus may result in incomplete clearance of *T. pallidum* from lesions, allowing the development of a chronic infection and the resulting multitude of clinical findings in congenital syphilis [128]. The increased production of inflammatory cytokines interleukin-2, interferon-$\gamma$, tumor necrosis factor-$\alpha$, and prostaglandins induced by fetal infection together with the intense inflammatory responses associated with activation of macrophages by treponemal lipoproteins may be responsible for fetal death or preterm delivery in a mother with primary or early secondary syphilis and severe growth restriction or some of the manifestations of congenital syphilis in the infant [36]. The resolution of the primary and the secondary manifestations of infection correlate with the development of cellular immune responses [10].

## Host Innate Immune Response

Although *T. pallidum* does not contain lipopolysaccharide, the lipoproteins and glycolipids present under the outer membrane have been shown to activate the innate inflammatory response via toll-like receptor 4 (TLR4) [129]. These lipoproteins are not surface-exposed; live *T. pallidum* elicits a lower inflammatory response than with *T. pallidum* lysates [10,124,130]. This feature may explain how live treponemes can persist in extracellular loci, yet elicit little or no inflammatory response, and may account for the pronounced systemic (Jarisch-Herxheimer) reaction observed soon after the initiation of penicillin therapy, in which dying treponemes release proinflammatory mediators in large quantities. Polymorphonuclear leukocytes ingest *T. pallidum*, incorporating them into phagocytic vacuoles where they are killed and digested. Overall, phagocytosis occurs relatively slowly and is facilitated by the presence of immune serum [131].

Numerous treponemes are needed to activate the phagocytic response, and small numbers of treponemes may escape recognition [132]. Lipoproteins of *T. pallidum* are thought to gain access to toll-like receptors on the surface of macrophages only after degradation of organisms in phagolysosomal vacuoles [10,124,130]. When this degradation occurs, macrophages are induced to produce tumor necrosis factor [132,133] and messenger RNA for interleukin-12 [134], which favors the development of $T_H1$-type immunity. The spirochete also has been shown to activate human promyelomonocytic cell line THP-1 cells in a CD14-dependent manner [135]. These findings support the concept that lipoproteins are the principal components of spirochetes responsible for innate immune activation. The direct interaction of *T. pallidum* with vascular endothelium also seems to be an important early event in the initiation of the host innate immune response to syphilitic infection [133]. A purified 47-kDa treponemal lipoprotein can activate human vascular endothelial cells to upregulate cell surface expression of intercellular adhesion molecule-1 and procoagulant activity [136]. These actions may contribute to the fibrin deposition and perivasculitis that are characteristic histopathologic findings in syphilis [10].

## Host Adaptive Immune Response

In acquired syphilis, IgM and IgG antibodies are detectable by the time the primary chancre appears, but humoral immunity is insufficient to control the infection. T cell–mediated immunity seems to be suppressed during the primary and secondary stages of infection [121]. Nevertheless, ultimate eradication of acute infection occurs only when T cells infiltrate syphilitic lesions, which leads to activation of macrophages and phagocytosis of antibody-opsonized treponemes.

### *Host Cell–Mediated Immune Response*

The lack of outer membrane immune targets has led *T. pallidum* to be labeled a "stealth pathogen." [10] The importance of cellular immunity in containing the infection and in its immunopathology is shown by the presence of granulomata, which, in the case of gummatous disease (see later), assume a necrotizing character [121]. T lymphocytes responsive to *T. pallidum* appear in syphilitic lesions as the number of treponemes decreases, suggesting a role of cellular immunity in controlling infection. In primary chancres, $CD4^+$ T cells and macrophages predominate, whereas in the lesions of secondary syphilis, most of the cellular infiltrate is composed of $CD8^+$ T cells; this is surprising because *T. pallidum* is believed to be mostly an extracellular pathogen. Increased expression of the $T_H1$ cytokines interleukin-2 and interferon-$\gamma$ are seen in lesions of primary and secondary syphilis, in humans and in the rabbit model [130,137,138]. Circulating T lymphocytes responsive to treponemal antigens can already be detected in late primary syphilis, but cell-mediated immune responses peak in the secondary stage. Clinically measurable delayed-type hypersensitivity to treponemal antigens appears only late in secondary syphilis and may be related to the onset of latency. Increased apoptosis of peripheral blood lymphocytes and $CD4^+$ T cells by a Fas-mediated pathway in patients with secondary early syphilis could account for the incomplete clearance of *T. pallidum* from the lesions, leading to the establishment of chronic infection [139]. Overall, however, the mechanisms that lead to latency are not understood [10].

### *Host Antibody–Mediated Humoral Immune Response*

Humoral immunity has been a subject of study in syphilis since the serendipitous discovery of antibody to cardiolipin by Wassermann early in the 19th century. Circulating

IgG and IgM antibodies to *T. pallidum* are detectable by the time the chancre appears (i.e., with the onset of primary syphilis), with antibodies to *T. pallidum* detected in 90% and antibody to cardiolipin detected in 75% of cases [140]. Antibodies to *T. pallidum* recognize a wide range of proteins [141], with the 47-kDa antigen being the most immunogenic [142]. Higher titers are reached as the infection disseminates in the secondary stage [143,144]. In primary syphilis, the main IgG subclass is IgG1, whereas in secondary syphilis, IgG1 and IgG3 predominate [145]. If the patient is treated adequately, IgM antibody declines during the next 1 to 2 years, but IgG antibody usually persists through the lifetime of the patient. The stages of syphilis evolve, despite the treponeme-specific antibody response [10].

The overall antibody response of congenitally infected infants parallels the response in acquired syphilis. IgM antibodies to specific *T. pallidum* proteins can often be detected in neonatal serum obtained at birth [146–149]. The range of IgM antibody responses to the proteins of *T. pallidum* in the sera of overtly infected newborns is comparable to that for disseminated (secondary) infection in adults [150]. The IgM response of the infant is distinct, however, from that of the mother and is uniformly directed against the 47-kDa immunodominant membrane lipoprotein antigen. As would be expected based on the transplacental transfer of IgG, the IgG levels and antigen specificity of infected infants largely match those of their mothers [148–150].

Human sera containing antibodies can immobilize *T. pallidum* in the presence of complement—the basis of the old *T. pallidum* immobilization test for diagnosing syphilis—and can block attachment of the organism to eukaryotic cells. Human immune serum facilitates uptake of *T. pallidum* by human polymorphonuclear leukocytes [132]. The antigens to which these immobilizing antibodies are directed are unknown. Only a small percentage of patients with primary syphilis have immobilizing antibodies [25,151]. *T. pallidum*–immobilizing antibody is also present in most patients who have active secondary syphilis [27]. Passive immunization of rabbits with large amounts of serum from rabbits that have recovered from experimental *T. pallidum* infection and are immune to rechallenge delays and attenuates infection, but does not prevent the development of syphilitic lesions [27,152,153]. Why the disease progresses despite abundant and even neutralizing antibody responses is unclear, but suggests that humoral immunity is insufficient to clear active infection and that cellular immunity is required [10].

*T. pallidum* contains a family of repeat genes, the *tpr* genes [10], which encode proteins homologous to the major surface proteins of *T. denticola* that mediate attachment to host tissue and function as porins [154]. Tpr proteins are immunogenic in rabbits, and one of them, TprK, has been shown to be a target for opsonic antibody. TprK differs in seven discrete variable regions, and in a rabbit model, antibodies to these variable regions offer protection against homologous, but not heterologous strains [147,155]. With successive passage, diversity is observed in the TprK V region genes [156]. Antigenic variation through gene conversion in infection has been hypothesized to be another mechanism by which the organism evades the host immune response, allowing for prolonged infection and persistence in the presence of a robust host response. The immune response to TprK seems to be a primary means of killing treponemes. T-cell responses apparently are directed against conserved epitopes of TprK, whereas opsonic antibodies are directed against variable region epitopes. This factor may account for the common clinical scenario of reinfection with syphilis. Similar mechanisms have been described for spirochetes of the genus *Borrelia*, which cause relapsing fever [124].

Secondary syphilis and congenital infection sometimes are accompanied by an immune-mediated nephrotic syndrome. This nephrosis characteristically responds rapidly to penicillin, and light microscopy reveals membranous glomerulonephritis with glomerular mesangial cell proliferation. The subendothelial basement membrane deposits contain IgG and C3 or only globulin. Acute syphilitic glomerulonephritis seems to be an immune complex disease in acquired [157–159] and congenital syphilis [160]. Similar immune complex–mediated processes may underlie other clinically apparent signs of congenital syphilis as well [161].

## IMMUNE-MEDIATED PROTECTION

Although patients who have been previously treated for syphilis can be reinfected, untreated patients seem to have at least a degree of immunity to repeated infection. In the 19th century in Dublin, Colles observed that wet nurses who breast-fed infants with congenital syphilis often developed chancres of the nipple, whereas the mothers of such infants did not, implying that they were somehow protected from repeated infection; this has become known as Colles' law [162,163]. Subsequent studies in which prisoner volunteers in the United States were inoculated with *T. pallidum* likewise showed that men with untreated syphilis did not develop chancres at the site of cutaneous inoculation, whereas men who had been treated for syphilis in the past (especially men who had been treated early during primary or secondary stages) and men who had not had the infection did develop infection [52].

Persons with untreated secondary syphilis or true latent infection are resistant to rechallenge with *T. pallidum*, as are individuals with untreated congenital syphilis [52]. This state has been referred to as "chancre immunity" or "chancre fast." Such protection from untreated previous disease represents only a relative resistance to reinfection, such that the development of a chancre with reinfection is unusual, but may simply depend on the challenge inoculum. This state of relative resistance applies to persons who maintain a reactive nontreponemal antibody test (serofast) and to individuals whose sera become nonreactive [164,165].

Physicians in the 19th century knew that a degree of maternal immunity is acquired during infection. In 1846, Kassowitz observed that the longer syphilis exists untreated in a woman before pregnancy occurs, the more likely it is that when she does become pregnant, her treponemes will be held in check, and the less likely it is that her fetus will die in utero or be born with congenital syphilis (Kassowitz's law) [1,162]. It remains unclear what

factors determine which mothers, particularly in the latent stage of infection, pass disease to their fetuses. It also is unclear why some infants who are infected in utero are born without any clinical manifestations, with the subsequent development of overt disease in the first weeks or months of life or even later at puberty.

Although active or prior syphilis modifies the response of the patient to subsequent reinfection, protection is only relative and is unreliable [10]. Rabbits immunized with irradiated *T. pallidum* display complete protective immunity to challenge [166]. Together, these findings argue that it should be possible to achieve protective immunity, possibly through vaccination [10].

## PATHOLOGY

Although there are many similarities in the pathology of acquired and congenital syphilis, there also are some key differences. Acquired syphilis is a lifelong infection that progresses in three clear characteristic stages [121,167]. After initial invasion through mucous membranes or skin, the organism undergoes rapid multiplication and is disseminated widely. Spread through the perivascular lymphatics and then through the systemic circulation probably occurs even before the clinical development of the primary lesion.

The patient manifests an inflammatory response to the infection at the site of the inoculation 10 to 90 days later, usually within 3 to 4 weeks. The resulting lesion, the chancre, is characterized by the profuse discharge of spirochetes, accumulation of mononuclear leukocytes, and swelling of capillary endothelia. The regional lymph nodes become enlarged as well, with the cellular infiltrate in the lymph node resembling that of the primary chancre lesions. Resolution of the primary lesion eventually occurs via fibrosis (scarring) at the primary chancre site and reconstruction of the normal architecture in the lymph node. Secondary lesions develop when tissues of ectodermal origin, such as skin, mucous membranes, and central nervous system (CNS), become infected with resulting vasculitis. The cellular infiltrate resembles that of the primary lesion, with the predominance of plasma cells, but CD8 T cells instead of CD4 T cells. There is little or no necrosis, and healing of secondary lesions occurs without scarring.

Tertiary syphilis seems to occur from chronic swelling of the capillary endothelium resulting in tissue fibrosis or necrosis and may involve any organ system. It often is asymmetric. Gummata are lesions typified by extensive necrosis, a few giant cells, and a paucity of organisms. They commonly occur in internal organs, bone, and skin. The other major form of tertiary lesion is a diffuse chronic perivascular inflammation, with plasma cells and lymphocytes but without caseation, which may result in an aortic aneurysm, paralytic dementia, or tabes dorsalis.

Congenital syphilis cannot be divided neatly into these three stages [168]. Because it is a result of hematogenous infection, dissemination is wide resulting in involvement of almost all viscera. Most pathologic studies were done on stillborn infants or infants who died early in life, producing significant heterogeneity in the findings secondary to varying length of infection before pathologic examination. Similar to the acquired form, in congenital syphilis an intense inflammatory response is also focused on the perivascular environment, rather than distributed throughout the parenchyma [162]. Bone, liver, pancreas, intestine, kidney, and spleen are involved most reproducibly and severely. Other tissues, such as the brain, pituitary gland, lymph nodes, and lungs, may be infected as well [169].

The grossly apparent clinical findings of a live-born infant with congenital syphilis are described later in this chapter. A stillborn infant with syphilis often has a macerated appearance, with a collapsed skull and protuberant abdomen. Erythroblastosis involving the placenta has been seen more commonly among stillborn infants with congenital syphilis than in infected live-born infants with or without clinical findings of syphilis at birth [170]. Live-born or stillborn, the placenta of infants with congenital syphilis is often large, thick, and pale. Spirochetes may be identified in placental tissue using conventional staining, although they may be difficult to visualize [55,63,171]. Nucleic acid amplification methods have successfully identified *T. pallidum* genome in involved placental specimens [172]. Three histopathologic features commonly are seen (Fig. 16–3): enlarged and hypercellular villi, proliferative fetal vascular changes, and acute and chronic inflammation of the villi [173,174]. The inflamed villi become enlarged and hypercellular and often have bullous projections [63,171]; these larger villi, with respect to the amount of blood in the capillaries, are the cause of the pallor [174]. In addition, an increased amount of connective tissue surrounds the capillaries and makes up the stroma.

The umbilical cord may exhibit significant inflammation with abscess-like foci of necrosis located within Wharton jelly, centered around the umbilical vessels resulting in what is termed *necrotizing funisitis* [175]. Macroscopically, the umbilical cord resembles a “barber’s pole”; the edematous portions have a spiral striped zone of red and pale blue discoloration, interspersed with

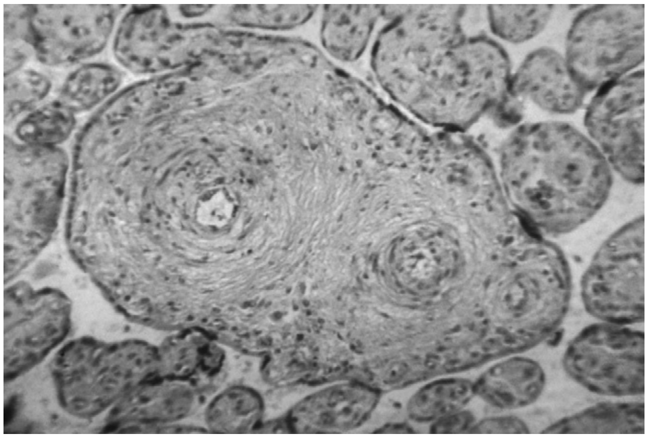

**FIGURE 16–3 Photomicrograph revealing cytoarchitectural changes seen in congenital syphilis of the placenta.** The chorionic villi are enlarged and contain dense laminated connective tissue, and the capillaries distributed throughout the villi are compressed by this connective tissue proliferation. (Hematoxylin and eosin stain; magnification 450×.) *(Courtesy of CDC/Susan Lindsley; 1971; Public Health Image Library #2347.)*

streaks of chalky white [174,176,177]. Histochemical staining and nucleic acid amplification approaches have shown spirochetes within the wall of the umbilical vessels [178]. Given these typical findings, placental and umbilical cord histopathology should be performed on every case of suspected syphilis, especially if the placenta is unexpectedly large.* Sheffield and colleagues [174] showed that the addition of histologic evaluation to conventional diagnostic evaluations improved the detection rate for congenital syphilis from 67% to 89% in live-born infants and 91% to 97% in stillborn infants.

The basic architecture of the fetal and infant tissue involved influences the ultimate pattern of macropathologic and micropathologic findings. The deposition of collagen around arteries of the spleen produces a typical onion-skin appearance, and liver and spleen are enlarged secondary to fibrosis [180].

A divergence of opinion still exists regarding the nature and precise extent of hepatic involvement in congenital syphilis. The traditional view has been that diffuse interstitial inflammation is present and can progress to disrupt the normal hepatic architecture by extensive scarring. Oppenheimer and Hardy [180] found that 15 of 16 livers from infants who died before 9 weeks of age were abnormal; lesions varied considerably in severity, but included inflammation in the interstitial stroma and perivascular network, especially in the area of the portal triads, with diffuse hepatitis and excessive extramedullary hematopoiesis [180]. Wright and Berry [181] found that 50 of 59 sections of livers from stillborn infants stained with hematoxylin and eosin were histologically normal, although silver stains revealed heavy infiltration with treponemes. The discrepancies in the observations of these studies may be related to the different ages of the patients and the severity of the infections. The patients described by Wright and Berry [181] were up to 1 year old. Gummata have rarely been described in the liver of infants with congenital syphilis; cirrhosis also seems to be uncommon [180]. As a result of liver and spleen fibrosis, extensive extramedullary hematopoiesis often accompanies congenital syphilis.

The gastrointestinal tract shows a pattern of mononuclear cell infiltration in the mucosa and submucosa, with subsequent thickening owing to the ensuing fibrosis. This pattern is most prominent in the small bowel [180,182,183]. An intense pancreatitis is often present, with a perivascular inflammatory infiltrate, obliteration of ductules and acini, reduction in the number of islets, and extensive fibrosis [180].

Renal involvement seems to be the consequence of injury to the glomeruli by immune complex deposition [159], just as has been described for the glomerulitis of secondary syphilis in adults [158]. An epimembranous glomerulopathy [184] is common and is associated with two different forms of immune complex injury, one involving complement deposition in addition to IgA, IgM, and IgG and the other involving immune complexes without complement deposition along the basement membrane [159]. A perivascular inflammatory infiltrate, consisting of plasma cells and lymphocytes involving the interstitial tissues, is prominent. The visceral and parietal epithelial cells of the glomeruli are swollen and increased in number. Increased matrix, collagen, and cells broaden axial regions in each tuft. Numerous electron-dense nodular deposits are noted on the epithelial aspect of the thickened glomerular basement membrane [159,184]. Elution studies have shown the presence of antitreponemal antibodies in the eluate and of treponemal antigen in the eluted sections [185]. A seemingly more rare proliferative glomerulonephritis also has been described, with mesangioendothelial proliferation and crescent formation [186].

*Pneumonia alba* of congenital syphilis is characterized by yellow-white, heavy, firm, and grossly enlarged lungs [123]. A marked increase in the amount of connective tissue in the interalveolar septa and the interstitium associated with collapse and loss of alveolar spaces explains the increased weight and density of the lung. This obliterative fibrosis of the lung is now reported only rarely [180].

Widespread involvement of bones is characteristic of congenital syphilis. Radiographs of long bones show evidence of osteochondritis and periostitis, especially in the long bones and ribs. Osteochondritis is recognized grossly by the presence of a moderate and irregular yellow line in the zone of provisional calcification. The trabeculae are irregular, discontinuous, and variable in size and shape. The excessive fibrosis occurring at the osseous-cartilaginous junction is termed *syphilitic granulation tissue* and contains numerous blood vessels surrounded by the inflammatory infiltrate [123]. The characteristic saw-toothed appearance, produced by irregularity in the provisional zone of calcification, corresponding to an irregularity in growth of capillaries, has been described historically, but is now uncommonly found in radiographs [187]. Small islands of cartilage may persist in the ossified bone [180]. A subperiosteal deposit of osteoid, which can completely encircle the shaft of the long bone, is a feature of periostitis [162]. An associated osteomyelitis (osteitis) usually is present and when it involves the long bones is called *diaphysitis* [188]. Microscopically, an inflammatory infiltrate with erosion of the trabeculae and prominent fibrosis is seen [187]. In the skull, the periosteal reaction eventually can lead to the radiographic feature of frontal bossing. The basic process of the osseous disturbance seems to involve a failure to convert cartilage in the normal sequence to mature bone. Controversy about the pathogenesis of these bone changes has been ongoing for years. One view is that the changes are specific results of local infection by the spirochete; the other is that they represent nonspecific trophic changes on endochondral bone formation caused by severe generalized disease. The fact that they heal without specific antibiotic therapy tends to favor the latter view [158].

The skin shows vesicular or bullous lesions, which have fluid rich in treponemes. Guarner and associates [182] reported that a constant feature throughout the dermal tissues was concentric macrophage infiltrate around vessels, giving an onion-skin appearance.

The neuropathologic features of congenital syphilis are comparable with those of acquired syphilis except that the parenchymatous processes (general paresis, tabes dorsalis) that were infrequently described in the older literature

*References 63, 171, 174, 176, 177, 179.

now are extremely rare. Meningeal involvement is apparent as a discoloration and thickening of the basilar meninges [123], especially around the brainstem and the optic chiasm. Microscopically, endarteritis typically is present, depending on the severity and chronicity of the infection and on the blood vessels involved. Various degrees of neuronal injury can ensue. As the infection resolves, fibrosis can occur, with formation of adhesions that obliterate the subarachnoid space, leading to an obstructive hydrocephalus or to various cranial nerve palsies. Interstitial inflammation and fibrosis of the anterior lobe of the pituitary gland, sometimes accompanied by focal necrosis, also have been reported among infants with congenital syphilis [189]. The posterior lobe remains unaffected. An evolving anterior pituitary gumma was noted at autopsy in a 3-day-old infant with congenital syphilis that did not respond to treatment [169].

# CLINICAL MANIFESTATIONS

Because of its protean clinical manifestations, syphilis, whether acquired or congenital, has been described as the "great imitator" [10,11]. A high index of suspicion is needed for the clinician to consider syphilis in the pregnant woman and the newborn infant.

## SYPHILIS IN PREGNANCY

Two caveats should be heeded by the clinician caring for pregnant women: (1) Any ulcer, regardless of location, that is indurated and indolent and fails to heal within 2 weeks warrants exclusion of syphilis as a diagnosis. (2) Any generalized skin eruption, regardless of its morphology, should be viewed as secondary (disseminated) syphilis until proved otherwise [190].

Pregnancy has no known effect on the clinical course of acquired syphilis. Untreated syphilis can profoundly affect pregnancy outcome, however [175,178,191–193]. One of the most common sequelae of untreated syphilis during pregnancy is spontaneous abortion during the second and early third trimesters [194]. Untreated maternal syphilis can result in preterm delivery, perinatal death, and congenital infection (see later). Antenatal ultrasonography can be a helpful adjunct in the diagnosis of fetal syphilis; hydramnios, fetal hydrops, enlarged placenta, hepatosplenomegaly, and bowel dilation have been described [190,195]. Ultrasonography performed in pregnant women with early syphilis has suggested that fetal hepatosplenomegaly can be an important early indicator of congenital infection.

Whether the patient is pregnant or not, it is characteristic for the course of untreated acquired syphilis to progress through three or four stages over many years. Most clinical definitions of acquired *T. pallidum* infection categorize early syphilis as including primary and secondary syphilis and early latent syphilis with a latency of less than 1 year [78] or less than 2 years (WHO) after infection. Late syphilis consists of late latent, tertiary, and—depending on nomenclature—quaternary syphilis (or metalues). This classification is an oversimplification and does not take into account the many variations in signs and symptoms in relation to timing of infection in any particular individual [196].

### Primary Syphilis in Pregnancy

The time between infection with syphilis and the start of the first symptom ranges from 10 to 90 days (average 21 days), at which point a dark red macule or papule develops at the site of inoculation and rapidly progresses to an erosion called a *chancre*. It usually occurs as a single lesion, but there may be multiple lesions [197]. The chancre increases in size to 0.5 to 2 cm over 1 to 2 weeks until a typical, indolent, well-circumscribed, flat ulcer with a yellow-coated base and an indurated, non-undermined wall results. Edema and bilateral painless lymphadenopathy follow. Chancres often are unrecognized in women because they cause no symptoms and because their location on the labia minora, within the vagina, or on the cervix or perineum makes detection difficult. As a result, only 30% to 40% of infected women are diagnosed in the primary stage [73,110]. Two thirds of extragenital chancres occur orally or periorally; most of the rest occur perianally. Chancres rarely occur on the lips, tongue, tonsil, nipple, or fingers. Because a chancre can appear 1 to 3 weeks before a serologic response, direct detection of the pathogen (e.g., by dark-field microscope) is vital in this phase of the disease [198]. The chancre lasts 3 to 8 weeks, and then heals without treatment. The mechanism for healing is obscure; it is believed that local immunity is partly responsible because secondary lesions appear during or after the regression of the primary one. If adequate treatment is not administered, however, the infection progresses to the secondary stage.

### Secondary Syphilis in Pregnancy

An infected woman may experience secondary disease, characterized by fever, fatigue, weight loss, anorexia, pharyngitis, myalgia, arthralgia, and generalized lymphadenopathy 2 to 10 weeks after the primary lesions. These constitutional symptoms are accompanied by various exanthems and alopecia. Because of the protean clinical manifestations, secondary syphilis is often misdiagnosed [199–201]. Lesions of secondary syphilis result from the dissemination of *T. pallidum* from syphilitic chancres, and the term *disseminated syphilis* probably would be more appropriate [202].

The rash of secondary syphilis [196], often the first clinical manifestation noticed, develops symmetrically in approximately 75% of untreated subjects and appears as rough, red, or reddish brown spots (syphilids); they occur most often on the palms, soles, and trunk, where they tend to follow skin lines. Rashes with a different appearance may occur on any part of the body, however, and pustular, papular, lichenoid, nodular, ulcerative, plaque-like, annular, and even urticarial and granulomatous forms can occur. The vesiculobullous eruption that is common in congenital syphilis rarely occurs in adults. Contrary to a widely held belief, the exanthema can itch, especially in dark-skinned patients. Often the rash is very faint and not recognized at all. Rashes associated with secondary syphilis can already appear as the chancre is healing (the chancre is still present in approximately 15%) or several weeks after the chancre has healed.

Various mucosal manifestations can be of diagnostic importance and are present in one third to one half of patients. Mucosal plaques (representing superficial mucosal

erosions) and syphilitic angina are the most frequent and can involve the oral cavity, vulva, vagina, or cervix. Localized enanthems or perlèche-like lesions are also possible. Expansive, smooth lesions and gray-white plaques are rare. Erythematous, moist plaques can occur in warm, moist intertriginous regions where initial papules enlarge and become exuberant, raised, wartlike lesions termed *condylomata lata* (often confused with condyloma acuminata, which are caused by human papillomavirus infection). Papules of the scalp can lead to "moth-eaten" alopecia. This hair loss can occasionally also affect eyebrows and eyelashes. All secondary lesions of the skin and mucous membranes are highly infectious [196].

Generalized lymphadenopathy, fever, malaise, splenomegaly, sore throat, headache, and arthralgia (with a noticeable nocturnal pattern) can be present [198]. Other organ involvement may include gastritis, hepatitis [203,204], glomerulonephritis or nephrotic syndrome [157,205], periostitis [206–208], uveitis, iritis, and meningitis [202]. *T. pallidum* has been isolated from the cerebrospinal fluid (CSF) of 30% of adults with untreated secondary syphilis [80]. The signs and symptoms of secondary syphilis usually resolve with or without treatment. Without treatment, however, the infection progresses to the latent and possibly late stages of disease [70].

### Latent Syphilis in Pregnancy

Subclinical or latent syphilis is defined as the period after infection when patients are seroreactive, but show no clinical manifestations of disease. This latent phase can last for years [193,209]. This latent period is sometimes interrupted during the first few (<4) years by recurrences of symptoms of secondary syphilis. Treponemes can still be present in the blood intermittently and be passed across the placenta to the fetus during latent syphilis in a pregnant woman. The first year after infection is considered early latent, and the subsequent period is late latent syphilis. This classification is based on the time period of communicability (not just to the fetus), which is higher in the first year after infection compared with later time points [50]. If the duration of syphilis infection cannot be determined, the disease is classified as latent syphilis of unknown duration. Approximately 60% of untreated patients in the late latent stage continue to have an asymptomatic course, whereas 30% to 40% develop symptoms of late or tertiary disease. Progression of disease from late latent to late symptomatic syphilis usually is prevented if appropriate antimicrobial therapy is given at this stage [50].

### Late Stages (Tertiary Disease) in Pregnancy

Knowledge about the clinical appearances of late stages of acquired syphilis comes from two prospective studies and one retrospective study [10]. Initiated in 1891, a Swedish study explored the hypothesis that the therapy of that time (mercury-containing antimicrobials and other heavy metals) caused more illness than the untreated infection [162]. This study followed approximately 2000 patients with early syphilis for more than 20 years and concluded that about one third of the patients developed tertiary complications if untreated. Mortality from untreated syphilis was 8% to 14%. In 1932, the U.S. Public Health Service initiated the infamous Tuskegee study, in which 412 African-American men with latent syphilis were monitored without treatment for 40 years, with 204 matched uninfected control subjects. After 15 years, three quarters of the infected men showed evidence of tertiary syphilis, 50% of which were cardiovascular complications [210]. A single retrospective study examined autopsy records of 77 patients with untreated tertiary syphilis. Of these, 83% had cardiovascular complications, 9% had gummatous involvement, and 8% had neurosyphilis [211].

The gummata of tertiary disease are nonprogressive, localized nodules that can have central necrosis. Because these lesions are relatively quiescent, the term *benign tertiary syphilis* often is used. Spirochetes are extremely sparse or absent. The gummatous reaction primarily is a pronounced immunologic reaction of the host.

Approximately 15% of untreated infected subjects develop neurosyphilis in the tertiary stage, but in persons infected with HIV manifestations of neurosyphilis can occur at any stage. Neurosyphilis may be asymptomatic or, if symptomatic, may have various manifestations. Classic manifestations include paralytic dementia, tabes dorsalis, amyotrophic lateral sclerosis, meningovascular syphilis, seizures, optic atrophy, and gummatous changes of the spinal cord. Neurosyphilis may resemble virtually any other neurologic disease. Cardiovascular involvement of tertiary syphilis most commonly involves the great vessels of the heart, in which syphilitic aortic and pulmonary arteritis develop. One of the complications of this involvement is aortic regurgitation. The inflammatory reaction also may cause stenosis of the coronary ostia, with resulting angina, myocardial insufficiency, and death [212].

## ACQUIRED SYPHILIS IN CHILDREN

Most recognized syphilitic disease in children is congenital (see next). Acquired syphilis in prepubertal children seldom is reported and is assumed to resemble the clinical course of acquired syphilis in adulthood. Children with acquired syphilis should be assumed to have been infected through sexual abuse, unless another method of transmission can clearly be identified [213–217].

## CONGENITAL SYPHILIS

The spectrum of congenital syphilis is similar in many ways to the spectrum of other congenital infections in which the infecting organism spreads hematogenously from the pregnant woman to involve the placenta and infect the fetus [168]. The extent of damage to the fetus presumably depends on the stage of development when infection occurs and the elapsed time before treatment is initiated. With infection early in pregnancy and in the absence of therapy, fetal demise with spontaneous abortion (often after the first trimester) or late-term stillbirth occurs in approximately 30% to 40% of cases, but premature delivery or neonatal death also can occur.* In liveborn infants, infection can be clinically recognizable or silent at birth (approximately two thirds of infected

*References 55, 72, 83, 162, 192, 218.

live-born infants are asymptomatic at birth, but then develop signs and symptoms sometimes decades later) [121].

The postnatal clinical course of congenitally acquired syphilis has been divided arbitrarily into early and late stages [10,121]. Clinical manifestations appearing within the first 2 years of life are designated early congenital syphilis, and manifestations occurring after this time are considered late congenital syphilis. The clinical manifestations of early congenital syphilis appear as a direct result of active infection with resulting inflammation. Infants can have hepatosplenomegaly, snuffles, lymphadenopathy, mucocutaneous lesions, osteochondritis and pseudoparalysis, edema, rash, hemolytic anemia, or thrombocytopenia, all of which usually appear within the first 2 to 8 weeks of life (Table 16–1). The clinical manifestations of late congenital syphilis represent the scars induced by initial lesions of early congenital syphilis or reactions to persistent and ongoing inflammation. These so-called stigmata of late congenital syphilis reflect the delayed expression of a prenatal insult in a fashion comparable with the occurrence of deafness beyond infancy that is related to congenital rubella. Manifestations of late congenital syphilis may involve the CNS, bones and joints, teeth, eyes, and skin; these manifestations may not become apparent until many years after birth (Table 16–2) [219–221].

## Early Congenital Syphilis

After fetal infection occurs, any organ system can be affected because of widespread spirochetal dissemination. The diagnosis of early congenital syphilis should be considered in any infant who is born at less than 37 weeks of gestation with no other apparent explanation or if unexplained hydrops fetalis or an enlarged placenta is present.

**TABLE 16–1** Clinical Manifestations of Early Congenital Syphilis*

| |
|---|
| Osteochondritis, periostitis |
| Snuffles, hemorrhagic rhinitis |
| Condylomata lata |
| Bullous lesions, palmar and plantar rash |
| Mucous patches |
| Hepatomegaly, splenomegaly |
| Jaundice |
| Nonimmune hydrops fetalis |
| Generalized lymphadenopathy |
| Central nervous system signs |
| Elevated cell count or protein in cerebrospinal fluid |
| Hematologic findings |
| Hemolytic anemia |
| Diffuse intravascular coagulation |
| Thrombocytopenia |
| Pneumonitis |
| Nephrotic syndrome |
| Placental villitis or vasculitis (unexplained enlarged placenta) |
| Intrauterine growth restriction |

**Arranged in decreasing order of importance.*
*Data from Rathbun KC. Congenital syphilis: a proposal for improved surveillance, diagnosis and treatment. Sex Transm Dis 10:102, 1983.*

**TABLE 16–2** Clinical Manifestations of Late Congenital Syphilis

| | |
|---|---|
| Dentition | Hutchinson teeth, mulberry molars (Moon, Fournier) |
| Eye | Interstitial keratitis, healed chorioretinitis, secondary glaucoma (uveitis), corneal scarring |
| Ear | Eighth nerve deafness |
| Nose and face | “Saddle nose,” protuberant mandible |
| Skin | Rhagades |
| Central nervous system | Mental retardation, arrested hydrocephalus, convulsive disorders, optic nerve atrophy, juvenile general paresis, cranial nerve palsies |
| Bones and joints | “Saber shins,” Higouménakis sign, Clutton joints |

In infancy, failure to move an extremity (pseudoparalysis of Parrot), persistent rhinitis (snuffles), a maculopapular or papulosquamous rash (especially in the diaper area), unexplained jaundice, hepatosplenomegaly or generalized lymphadenopathy, or anemia or thrombocytopenia of uncertain cause should raise suspicion of congenital syphilis (see Table 16–1). The abnormal physical and laboratory findings in early congenital syphilis are varied and unpredictable. The onset of most clinical findings of early congenital syphilis is between birth and about 3 months of age, with most cases occurring within the first 8 weeks of age [159,178,180,187,222–225].

### *Intrauterine Growth Restriction*

Intrauterine growth restriction may be present at birth [211]. The effect of syphilis on the growth of the fetus in utero is likely to be related to the timing and severity of the fetal infection. In a carefully performed quantitative morphologic study, Naeye [226] showed that syphilitic infection in utero did not seem to have a significant effect on the growth of the fetus, as manifested by a study of 36 perinatal deaths associated with congenital syphilis. Naeye’s findings were similar to his previous results that showed a relative lack of effect on fetal growth from toxoplasmosis, contrasting with the intrauterine growth restriction associated with rubella and cytomegalovirus infections [226]. Case reports have indicated, however, that newborns with congenital syphilis were small for their gestational age [227]. Whether small size for gestational age is the result of syphilitic infection or other cofactors (e.g., use of illicit intravenous drugs by the mother) [228] that affect fetal growth is unknown. Historically, a severely infected infant with congenital syphilis has been described as a premature infant with marasmus, a pot belly, “old man” facies, and withered skin [162]. The degree of such extreme early-onset failure to thrive has been correlated with the frequently encountered pathologic finding of intense pancreatitis and inflammation of the gastrointestinal tract [180]. Rectal bleeding resulting from syphilitic ileitis with ulcer formation and associated intestinal obstruction has also been reported to be linked to this appearance [159]. Finally, involvement of the anterior pituitary gland in congenital syphilis can manifest as persistent hypoglycemia beyond the early neonatal period and, through such endocrine abnormalities, contribute to the failure to thrive [189].

## *Mucocutaneous Manifestations*

Mucous patches may be seen in the mouth and genitalia [211,229]. Mucous patches in the mouth are more prevalent in infants with severe systemic disease [230]. After the first 2 or 3 months of life, condylomata can arise on such affected mucous membranes or other areas of skin affected by moisture or friction (e.g., the perioral area, especially the nares and the angles of the mouth, and the perianal area) [231,232]. These highly infective areas are flat or wartlike and moist. Condylomata can be single or multiple and frequently occur in the absence of other signs of infection. Rhinitis, coryza, or snuffles (Fig. 16–4) indicates involvement of the upper respiratory tract mucosa. This manifestation usually appears in the 1st week of life and seldom later than the 3rd month. It was reported in two thirds of patients in the early literature [233], but now seems to be less common [229]. A mucus discharge develops, with character similar to that of discharge in upper respiratory tract infections, but is more severe and persists longer than in the common cold. The discharge can become progressively more profuse and occasionally is blood-tinged. Secondary bacterial infection can occur, causing the discharge to become purulent. If ulceration of the nasal mucosa is sufficiently deep and involves the nasal cartilage, a saddle-nose deformity, one of the later stigmata of congenital syphilis, can result. Snuffles also has been associated with laryngitis and an aphonic cry [229,234].

A syphilitic rash appears in 70% of infected infants [235]. It may be apparent at birth or develop during the first few weeks of life, usually 1 to 2 weeks after the onset of rhinitis [229,234]. The typical skin eruption consists of small, oval, copper-red maculopapular lesions (reminiscent of secondary acquired syphilitic lesions) that subsequently become coppery brown [232]. The hands and feet often are most severely affected. As the rash changes color, very fine superficial desquamation or scaling can occur, particularly on the palms and soles (Fig. 16–5). If the rash is present at birth, it often is widely disseminated and bullous and is called *pemphigus syphiliticus*; it typically involves the palms and soles (Fig. 16–6) [232]. The lesions vary in size and can contain a cloudy hemorrhagic fluid that teems with treponemes. When these bullae rupture,

**FIGURE 16–5** This newborn presented with symptoms of congenital syphilis that included lesions on the soles of both feet. *(Courtesy of CDC; 1970; Public Health Image Library #4148.)*

**FIGURE 16–4** The face of a newborn infant with congenital syphilis displaying snuffles. *(Courtesy of CDC/Dr. Norman Cole; 1963; Public Health Image library #2246.)*

**FIGURE 16–6** This newborn infant with congenital syphilis displays multiple, punched-out, pale, blistered lesions on the ear and the bridge of the nose; also shown is an associated desquamation of palms and plantar surfaces of the feet. *(From Battin M, Voss L. Beware of infants with respiratory distress, rash, and hepatomegaly at birth: a case of congenital syphilis. N Z Med J 120:U2448, 2007.)*

they leave a denuded area that can undergo extensive maceration and crusting. Pemphigus syphiliticus evolves over 1 to 3 weeks and is followed by desquamation and crusting. As the rash fades, the lesions become coppery or dusky red, and pigmentation may persist.

Other maculopapular types of eruptions are also found in early congenital syphilis. The lesions can be annular or circinate or can have the appearance of any other kind of lesion seen in acquired secondary syphilis. Petechial lesions can result from thrombocytopenia. Generalized edema can also be present [229,236] as a result of hypoproteinemia related to renal or hepatic disease. Ectodermal changes in syphilitic infants include suppuration and exfoliation of the nails, loss of hair and eyebrows, choroiditis, and iritis [237]. Fissures develop around the lips, nares, and anus. They bleed readily and heal with scarring. A cluster of scars radiating around the mouth is termed *rhagades* and is a characteristic of late congenital syphilis. Comparable eruptions also can be found in other body folds or intertriginous areas, but are considered to be more characteristic of the later stage of early congenital syphilis. Healing, with possible desquamation and crusting of the various skin lesions, occurs over 1 to 3 weeks [238,239]. All mucocutaneous lesions and discharges contain abundant spirochetes and are contagious via direct contact [233].

### Hepatomegaly, Hepatitis, Splenomegaly, and Lymphadenopathy

Hepatomegaly is present in nearly all infants with congenital syphilis and may occur in the absence of splenomegaly, although the reverse is not true (in contrast to congenital cytomegalovirus infection) [229]. Hepatomegaly and ascites are attributed largely to heart failure, but may be caused in part by hepatic infection and extramedullary hematopoiesis. Maternal treatment can interrupt this progression, but is less likely to be successful when fetal hepatomegaly and ascites have developed [240]. Hepatitis seems to be an early manifestation and can be detected as elevation of transaminase levels even in fetal blood. Neonatal syphilitic hepatitis is associated with visible spirochetes on biopsy specimen of liver tissue. Jaundice, which has been recorded in 33% of patients [229], can be caused by syphilitic hepatitis or by the hemolytic component of the disease and can be associated with elevation predominantly of direct or indirect bilirubin levels. Jaundice may be the only manifestation of the disease. The prothrombin time may be delayed [241]. Hepatic dysfunction in the form of elevated serum aminotransferases, alkaline phosphatase, and direct bilirubin initially can worsen with initiation of penicillin therapy and can persist for several weeks [241–243].

Splenomegaly is present in half of cases, and generalized nonsuppurative adenopathy, including epitrochlear sites, is present in some cases [211,229]. The lymph nodes themselves can be 1 cm in diameter and typically are nontender and firm. If an infant has palpable epitrochlear nodes, the diagnosis of syphilis is highly probable [121]. Generalized enlargement of the lymph nodes is rare in neonates and young infants with congenital syphilis.

### Hematologic Manifestations

Anemia, thrombocytopenia, leukopenia, or leukocytosis are common findings in congenital syphilis [222]. A characteristic feature in the immediate newborn period is that of a Coombs-negative hemolytic anemia. The hemolytic process is often accompanied by cryoglobulinemia, immune complex formation, and macroglobulinemia. The hemolysis, similar to the liver disease, is refractory to therapy and may persist for weeks. After the neonatal period, chronic nonhemolytic anemia can develop, accentuated by the usual physiologic anemia of infancy [236,244]. Other findings include polychromasia and erythroblastemia. This pattern of anemia and erythropoietic response historically led to confusion with erythroblastosis fetalis [162]. Although the leukocyte count usually falls within the normal range [236], leukopenia, leukocytosis, and a leukemoid reaction all can occur [229]. Lymphocytosis and monocytosis may be features. Thrombocytopenia, related to decreased platelet survival rather than to insufficient production of platelets, often is present and can be the only manifestation of congenital infection. Hemophagocytosis has been described and may play an important role in the pathogenesis of anemia and thrombocytopenia [245]. Hydrops fetalis also is a manifestation of congenital syphilis in newborns [246]. Paroxysmal nocturnal hemoglobinuria is a late manifestation of congenital syphilis [247,248]. Hydrops fetalis, or diffuse edema, results from anemia-related congestive heart failure, and a negative Coombs test in the setting of hydrops strongly suggests congenital syphilis [246].

### Bone Involvement

Bone findings [249] are a frequent manifestation of early congenital syphilis and occur in 60% to 80% of untreated cases. It may be the only abnormality seen in infants born to mothers with untreated syphilis and usually occurs as multiple and symmetric lesions. Overall, bone abnormalities are due to periostitis and cortical demineralization mostly in the metaphyseal and diaphyseal portions of long bones and osteochondritis, which affects the joints, primarily knees, ankles, wrists, and elbows. Characteristically, bone involvement in periostitis is widespread; the femur and humerus are affected most often, but the cranium, spine, and ribs also are affected [249]. The earliest and most characteristic changes are found in the metaphysis, with sparing of the epiphysis [249]. The changes are nonspecific and variable, ranging from radiopaque bands to actual fragmentation and apparent destruction with mottled areas of radiolucency.

Frequently, an enhanced zone of provisional calcification (radiopaque band) is associated with osteoporosis immediately beneath the dense zone. Variations of these paretic changes are seen, including peripheral (lateral) paresis only and alternating bands of density sandwiching a paretic zone [188]; this may appear smooth or serrated. The serrated appearance is known as Wegner sign and represents points of calcified cartilage along the nutrient cartilage canal. Although this sign now is uncommon, it can still be seen on radiographs of stillborn infants with congenital syphilis. A zone of rarefaction at the

metaphysis may also be seen, which represents syphilitic granulation tissue containing a few scattered calcified remnants and a mass of connective tissue displaying areas of perivascular infiltration of small round cells. Irregular areas of increased density and rarefaction produce the moth-eaten appearance on the radiograph.

The demineralization and osseous destruction of the upper medial tibial metaphysis is called Wimberger sign (Fig. 16–7) [234]. Rarely, similar changes may occur at the upper ends of the humeri. Epiphyseal separation may occur as a result of a fracture of the brittle layer of calcified cartilage. Irregular periosteal thickening also is common. The changes usually are present at birth, but may appear in the first few weeks of life. Focal areas of patchy cortical radiolucency with spreading of the medullary canal and irregularity of the endosteal and periosteal aspects of the cortex can be seen on radiographs. In severe cases, the radiolucent areas that probably represent a growth arrest abnormality can appear as columns, giving a "celery stick" appearance of alternating bands of longitudinal translucency and relative density [234]. The inflammatory reaction in the diaphysis stimulates the periosteum to lay down new bone. The single or multiple layers of periosteal new bone extend along the cortex of the entire diaphysis. In contrast to the other two forms of osseous involvement (metaphyseal dystrophy and osteitis-like dystrophy), diaphyseal abnormalities are less often present at birth. Single bone involvement is unique, but solitary involvement of the radius has been described [250].

**FIGURE 16–7** Anteroposterior film of both lower extremities of a 1-month-old infant with congenital syphilis, showing demineralization and osseous destruction of the proximal medial tibial metaphysis bilaterally (Wimberger sign).

Solomon and Rosen [251,252] reported that in more than one third of 112 infants with congenital syphilis, radiographic findings were consistent with trauma of bone made more fragile by syphilitic infection. Although the above-described findings of periostitis require about 16 weeks for radiographic diagnosis, osteochondritic events in the major joints can be evident radiographically 5 weeks after fetal infection has occurred [253]. Involvement of the metacarpals, metatarsals, or proximal phalanges of the hand is rare. Dactylitis appears radiologically as a spindle-shaped enlargement of the bone and can occur from the ages of 3 to 24 months [254]. Unusual manifestations also have been reported. A case of syphilitic arthritis of the hip and elbow in association with osteomyelitis of the femur and humerus has been described in the immediate newborn period [255,256].

Obstetric radiography allows for in utero diagnosis of fetal syphilis by showing periosteal cloaking [257]. Maternal treatment has been associated with radiologic resolution of these lesions. Bone scans have been performed in very few patients; they reveal diffuse abnormalities when performed, but such scans are neither helpful nor recommended [258–260]. Because of their frequency and early appearance, the radiographic changes in the bones of osteochondritis and periostitis are of diagnostic value [187]. The correlation between the clinical and the radiologic findings is poor, however, inasmuch as other areas of bone involvement can look more severely affected on radiographs even though no clinical signs suggest their presence.

Most bone lesions are not clinically discernible except in pseudoparalysis of Parrot [261,262], in which the bony changes or a superimposed fracture, or both, lead to pain, causing the infant to refuse to move the involved extremity. Clinically, it can manifest as irritability in an infant a few weeks old who does not move one of the limbs [227]. Upper extremities are affected more frequently than lower extremities, and unilateral involvement predominates. This clinical picture can mimic Erb palsy, but rarely is present at birth. Cases where pseudoparalysis of Parrot has been the only presenting symptom in a newborn with congenital syphilis have been described and should not be missed [263]. Bony involvement usually resolves spontaneously (i.e., even without therapy) during the first 6 months of life [211,227,261,264].

### *Nervous System and Ocular Manifestations*

Neurologic manifestations, although well documented in the earlier literature, are now less frequently reported [265]. Without therapy, approximately 15% of infants with congenital syphilis develop findings such as meningitis, meningeal irritation, bulging fontanelles, cranial nerve palsies, seizures, hydrocephalus, or abnormal pituitary function [211].

There are two primary clinical presentations of neurosyphilis, although overlap may be considerable. Acute syphilitic leptomeningitis appears during the first year of

life, usually between 3 and 6 months of age. Signs can suggest acute bacterial meningitis, including a stiff neck, progressive vomiting, Kernig sign, bulging fontanelles, separation of the suture, and hydrocephalus [265]. In contrast to this clinical picture, CSF reveals abnormalities consistent with an aseptic meningitis, with approximately 200 mononuclear cells/mm$^3$, a modest increase in protein (50 to 200 mg/dL), and a normal glucose value. The CSF Venereal Disease Research Laboratory (VDRL) test is positive. This is the one form of CNS involvement that responds to specific therapy [211,234,265].

Chronic meningovascular syphilis generally manifests toward the end of the 1st year of life and can have a protracted course, resulting in progressive hydrocephalus, cranial nerve palsies or vascular lesions of the brain, and gradual intellectual deterioration [265]. The hydrocephalus is of low grade, progressive, and communicating as a result of obstruction in the basilar cisternae. Cranial nerve palsies and seizures can complicate the picture. The seventh cranial nerve most often is involved, but cranial nerves III, IV, and VI also can be affected. Optic atrophy can be preceded by papilledema.

Various cerebrovascular syndromes have been described, but they are rare. Cerebral infarction results from syphilitic endarteritis and can occur between the 1st and 2nd years of life, commonly manifesting as acute hemiplegia. Convulsions frequently complicate this clinical picture. In addition, involvement of the pituitary gland in congenital syphilis is common, occurring in approximately 40% of autopsy cases, and consists of interstitial inflammation and fibrosis with gumma formation in the anterior lobe. Clinical disease in affected infants is manifested by persistent hypoglycemia and diabetes insipidus [189,266].

Because of the wide range of normal values for CSF protein, red blood cells, and white blood cells (WBCs) in the neonatal period, it has been difficult to define unequivocally the proportion of infants with congenital syphilis who have abnormalities of these laboratory values. Current consensus [83] identifies an abnormal CSF WBC count in infants being evaluated for possible congenital syphilis as greater than 25 cells/mm$^3$ and abnormal protein as greater than 150 mg/dL (>170 mg/dL if the infant is premature).

A reactive CSF VDRL test is considered to be specific for neurosyphilis in older children and adults. In neonates, the significance of a reactive CSF VDRL test is suspect, however, because maternal nontreponemal IgG antibodies can pass from maternal serum to fetal and neonatal serum and then diffuse into the CSF. Children may fail to have a reactive VDRL test on initial examination and still develop signs of neurosyphilis later. Using rabbit infectivity testing, which involves the inoculation of CSF into rabbits to determine the presence of the spirochete in the CSF specimen, Michelow and coworkers [267] found that CNS invasion with *T. pallidum* occurs in 41% of infants who have clinical, laboratory, or radiographic abnormalities of congenital syphilis. None of these infants had clinical signs of neurologic disease. When compared with isolation of spirochetes in CSF by rabbit inoculation, the sensitivity and specificity in CSF of a reactive VDRL test, elevated WBC count, and elevated protein were 54% and 90% for reactive VDRL test, 38% and 88% for elevated WBC count, and 56% and 78% for elevated protein. CSF findings consistent with neurosyphilis are very common findings among infants with other clinical signs of congenital syphilis and are present in approximately 8% of asymptomatic infants born to mothers with untreated early syphilis [190,211,267].

Involvement of the eye in early congenital syphilis is rare. Chorioretinitis, salt-and-pepper fundus, glaucoma, uveitis, cataract [268], and chancres of the eyelid have been described [162]. Involvement by syphilis leads to a granular appearance of the fundus; pigmentary patches of various shapes and colors are seen in the periphery of the retina [162]. Young infants rarely manifest the signs of photophobia and diminution in vision that occur in older patients. Congenital glaucoma can occur and should be a diagnostic consideration in the presence of blepharospasm, cloudy cornea, enlarged cornea (diameter >12 mm), and excessive tearing. Inflammation of the uveal tract (including the iris and ciliary body anteriorly and the choroid posteriorly) affects the retina because of the close anatomic relationship of the cornea to the structures of the uveal tract [162]. Consequently, chorioretinitis rather than uveitis is the more commonly diagnosed ocular problem in infancy [268]. Rarely, a chancre of the eyelid appears 4 weeks after birth, presumably resulting from recently developed syphilitic lesions of the maternal genitalia [162].

### Other Findings

Fever has been reported to accompany other signs of congenital syphilis in infants beyond the immediate newborn period [242,269]. Pneumonia alba, a fibrosing pneumonitis, occurs in a few cases in the developed world, but still represents a frequent finding in developing countries [121]. The classic radiographic appearance is one of complete opacification of both lung fields. More commonly, a diffuse infiltrate involving all lung areas is seen on chest radiograph. At autopsy, pneumonia alba consists of a focal obliterative fibrosis with scarring and thickening of alveolar walls with loss of alveolar spaces. Follow-up evaluation of children who have recovered from congenital syphilis has shown that at least 10% may develop chronic pulmonary disease, particularly if they were premature and required mechanical ventilation [121].

The clinical picture of nephrotic syndrome may appear at 2 or 3 months of age, the predominant manifestation being generalized edema, including pretibial, scrotal, and periorbital areas, together with ascites [270–274]. Rarely, the infant can have hematuria with less severe proteinuria, but more profound azotemia, which suggests that a glomerulitis predominates. Myocarditis [180] has been found at autopsy in approximately 10% of infants who die, although the clinical significance of this finding is unclear. Gastrointestinal presentations include rectal bleeding owing to syphilitic ileitis, necrotizing enterocolitis, malabsorption secondary to fibrosis of the gastrointestinal tract, and fetal bowel dilation seen on antenatal ultrasonography. Some children with symptomatic congenital syphilis also may present with sepsis resulting

from other bacteria, including *Escherichia coli*, group B streptococci, and *Yersinia* species, presumed to be secondary to the breakdown of the gastrointestinal mucosal barrier [223,275].

## Late Congenital Syphilis

As noted earlier, the clinical manifestations of late congenital syphilis are stigmata that represent scars induced by the initial lesions of early congenital syphilis or reactions to persistent and ongoing inflammation (see Table 16–2). In patients older than 2 years, late congenital syphilis can be manifested by (1) the stigmata of the disorder that represent the scars of initial lesions or developmental changes induced by the early infection; (2) ongoing inflammation, although *T. pallidum* is not demonstrable; or (3) a persistently positive result on treponemal serologic tests for syphilis in the absence of apparent disease [78,83]. Treatment of neonates with congenital syphilis has nearly eliminated these consequences in developed countries, but late manifestations occur in approximately 40% of untreated survivors. Many of these manifestations do not seem to be reversible with antibiotic treatment [121,276].

### *Mucocutaneous Manifestations*

An infrequent sign of late congenital syphilis is linear scars that become fissured or ulcerated, resulting in deeper scars called rhagades. These scars are located around body orifices, including the mouth, nostrils, genitalia, and anus [162]. The sequelae of syphilitic rhinitis include failure of the maxilla to grow fully, resulting in a concave configuration in the middle section of the face with relative protuberance of the mandible and an associated high palatal arch. Inflammation of the nasal mucosa can affect the cartilage, leading to destruction of the underlying bone and perforation of the nasal septum. The resulting depression of the roof of the septum gives the appearance of a saddle nose [162].

### *Bone and Joint Findings*

Bone involvement in late congenital syphilis is infrequent compared with the frequent occurrence of abnormalities in early congenital syphilis [66,162]. The sequelae of prolonged periosteal reactions can involve the skull, resulting in frontal bossing ("Olympian brow"); anterior bowing of the mid-tibia, resulting in "saber shin"; or thickening of the sternoclavicular portion of the clavicle, resulting in a deformity called Higouménakis sign [219]. For unknown reasons, the last-named finding tends to occur only on the side of dominant handedness. Joint involvement is rare. Clutton joints are symmetric, painless, sterile, synovial effusions, usually localized to the knees. Radiographs do not show involvement of the bones, and examination of the joint fluid reveals a few mononuclear cells [277,278]. Perforation of the hard palate almost is pathognomonic of congenital syphilis [162,279].

### *Dental Involvement*

Syphilitic vasculitis around the time of birth can damage the developing tooth buds and lead to dental anomalies. Hutchinson teeth are abnormal permanent upper central incisors that are peg-shaped and notched, usually with obvious thinning and discoloration of enamel in the area of the notching; they are widely spaced and shorter than the lateral incisors; the width of the biting surface is less than that of the gingival margin (Fig. 16–8) [280]. Mulberry molars (also known as Moon or Fournier molars) are multicuspid first molars in which the tooth's grinding surface, which is narrower than that at the gingival margin, has many small cusps instead of the usual four well-formed cusps (Fig. 16–9). The enamel itself tends to be poorly developed [162,219]. X-ray studies can lead to the diagnosis, even while deciduous teeth are in place. Deciduous teeth are largely unaffected except for a possible predisposition to dental caries [162].

**FIGURE 16–8 Photograph of Hutchinson teeth resulting from congenital syphilis.** Hutchinson teeth are a congenital anomaly in which the permanent incisor teeth are narrow and notched. Note the notched edges and "screwdriver" shape of the central incisors. *(Courtesy of CDC/Susan Lindsley; 1971; Public Health Image Library #2385.)*

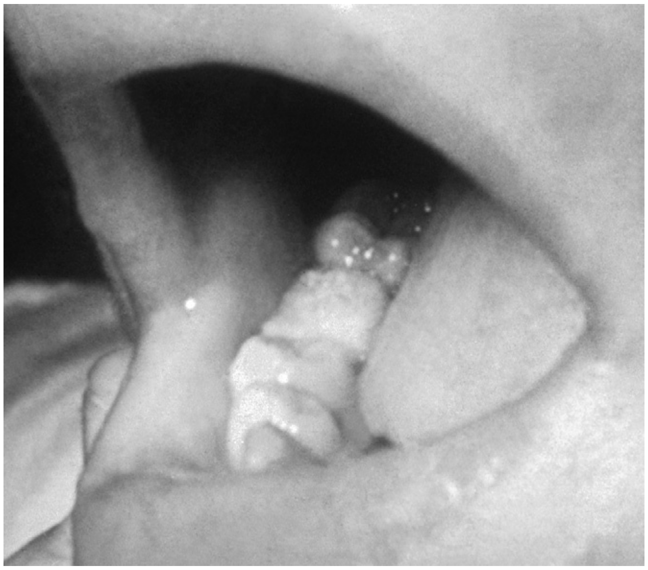

**FIGURE 16–9 Photograph of mulberry molar resulting from congenital syphilis.** Mulberry molar is a condition where the first lower molar tooth has become dome-shaped because of malformation caused by congenital syphilis. *(Courtesy of CDC/Susan Lindsley; 1971; Public Health Image Library #2386.)*

Putkonen [276] examined 30 children whose infected mothers had received penicillin during the latter half of pregnancy and an additional 36 children whose initial therapy for congenital syphilis was initiated during the first few months of life. He noted distinct syphilitic dental changes in 7 of 15 children whose treatment began at age 4 months or later, but in none of the children whose mothers had received treatment during the last half of pregnancy or before age 3 months. He concluded that early treatment prevented the dental changes of syphilis.

### Nervous System, Ear, and Ocular Manifestations

The same manifestations of neurosyphilis seen in acquired syphilis may occur in congenital syphilis and can include mental retardation; arrested hydrocephalus; convulsive disorders; juvenile general paresis; and cranial nerve abnormalities, including deafness and blindness, which is due to optic nerve atrophy [265]. Paresis is seen more frequently and tabes dorsalis is seen less frequently in the congenital form than in the acquired form of the disease [102,162,233]. Overall, these findings are uncommon in cases described during the last 50 years [281].

Eighth cranial nerve deafness develops in approximately 3% of untreated cases. The Hutchinson triad comprises Hutchinson teeth, interstitial keratitis, and eighth nerve deafness [102], with eighth nerve deafness the least common component of the triad. The histopathologic features of luetic involvement of the temporal bone include mononuclear leukocytic infiltration and obliterative endarteritis, with involvement of the periosteal, endochondral, and endosteal layers of bone. Osteochondritis affecting the otic capsule can lead to cochlear degeneration and fibrous adhesions, resulting in eighth nerve deafness and vertigo. Although deafness usually occurs in the first decade, it may not appear until the third or fourth decade of life. It often starts with sudden loss of high-frequency hearing, with normal conversational tones affected later. It may respond to long-term corticosteroid therapy [219,282,283].

Eye involvement can lead to interstitial keratitis, secondary glaucoma, or corneal scarring. In keratitis, a severe inflammatory reaction begins in one eye, detectable as ground-glass appearance of the cornea (Fig. 16–10), accompanied by vascularization of the adjacent sclera; this generally becomes bilateral during the ensuing weeks or months. Spirochetes have not been detected [284]. Symptoms include photophobia, pain, excessive lacrimation, and blurred vision. Patients can have conjunctival injection, miosis, keratitis, anterior uveitis, or a combination of these findings. Interstitial keratitis is considered preventable if treatment is given before age 3 months [276]. Interstitial keratitis usually appears at puberty and is not affected by penicillin therapy, but responds transiently to corticosteroid treatment [285]. It often has a relapsing course that can result in secondary glaucoma or corneal clouding. Early retinal involvement or hydrocephalous can lead to optic atrophy [102].

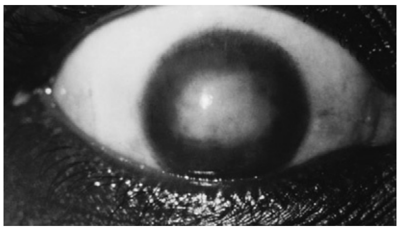

**FIGURE 16–10 Photograph depicts the presence of a diffuse stromal haze in the cornea of a child, known as interstitial keratitis, which was due to late-stage congenital syphilis.** Interstitial keratitis, which is an inflammation of the connective tissue structure of the cornea, usually affects both eyes and can occur as a complication to congenital or acquired syphilis. Interstitial keratitis usually occurs in children older than 2 years. *(Courtesy of CDC/Susan Lindsley; 1973; Public Health Image Library #6837.)*

## DIAGNOSIS

The diagnosis of congenital or acquired syphilis is usually suspected based on clinical and epidemiologic findings and ideally is confirmed by direct identification of treponemes in clinical specimens, supported by positive serologic findings. In clinical practice, diagnosis is most often made, however, by clinical findings supported by serologic methods alone [286,287].

### DIRECT IDENTIFICATION

Currently available methods to identify *T. pallidum* in clinical specimens obtained from a primary chancre or active secondary lesions in the mother or any lesion, body fluid, or tissue biopsy specimen in an infant are (1) dark-field microscopy, (2) direct fluorescent antibody staining, (3) demonstration of the organism by special stains on histopathologic examination, (4) the rabbit infectivity test, and (5) detection of *T. pallidum* DNA [50,58,121,211,288]. (*Note*: Gloves should be worn when examining suspected syphilitic lesions and when performing dark-field examinations). Ideal starting material is lesion exudate or tissue material, including placenta or umbilical cord. Specimens can also be scraped from moist mucocutaneous lesions or aspirated from a regional lymph node. The scaly eruption of syphilis is not a good source of material for dark-field microscopy. Bullae should be aspirated with a sterile syringe and needle. Papules or condylomata should be cleaned thoroughly with physiologic saline solution with no additives, then abraded with a gauze until oozing occurs, and scraped firmly to collect serum rather than blood.

For dark-field microscopy, a sterile glass slide is applied to the exudate, which is covered by a drop of normal saline and placed under a coverslip. Evaluation of these slides requires much experience and must be done immediately (within 5 to 10 minutes) on freshly obtained tissue because these corkscrew-shaped organisms are identified by their characteristic movements. Because about $10^5$ organisms/mL are required for visualization, a negative dark-field examination does not rule out syphilis. Nonpathogenic commensal spirochetes (e.g., of the oral flora) can be confused with *T. pallidum* even by experienced examiners. Examination of oral lesions with the dark-field microscope should not be done for this reason, unless direct fluorescent antibody techniques are employed that allow the examiner to distinguish *T. pallidum* from

nonpathogenic treponemes. For experienced examiners, the sensitivity of the dark-field microscope is 79% to 97%, and specificity is 77% to 100%. If the result of the initial dark-field examination is negative, it should be repeated on at least 2 successive days to confirm a negative result. Although not evaluated for use in specimens from newborns, a modification called the "dark ground" microscopy method has been used in adults with primary and secondary syphilis, with sensitivities of 97% and 84% and with good specificity [289]. This rapid and sensitive test also requires a dark-field microscope and trained personnel.

If a dark-field microscope is unavailable, a direct fluorescent antibody stain for *T. pallidum* can be employed [178]. Exudate is collected in capillary tubes or slides and stained with specific antibody in a direct or indirect fluorescent antibody test for *T. pallidum*. These tests use either monoclonal or polyclonal antibodies against *T. pallidum* that are directly fluorescein-tagged or use a second fluorescein-tagged antibody (indirect fluorescent antibody) to detect the primary antibody-antigen complex [290]. The advantage of immunofluorescent methods over dark-field microscopy is that slides are more permanent and can be mailed to reference laboratories for review by experts [178,291,292].

The rabbit infectivity test is still the gold standard for the identification of viable *T. pallidum* in clinical specimens, having a sensitivity of less than 10 organisms [52,62,80,149,293]. It involves intratesticular inoculation of the specimen into a rabbit and awaiting serologic seroconversion and orchitis with subsequent visualization of motile spirochetes by dark-field microscope in testicular tissue. The rabbit infectivity test is performed only in research laboratories, however, and may take several months for identification of the organism.

Polymerase chain reaction (PCR)–based tests eventually may replace the rabbit infectivity test as the reference standard for syphilis diagnostic tests [45,58,294–296]. The PCR assay is said to be capable of detecting an amount of purified treponemal DNA equivalent to that of only a few organisms (about 0.01 pg) [58]. Compared with isolation of the organism by rabbit infectivity testing, the sensitivity of PCR on CSF was 65% to 71%, and specificity was 97% to 100% [149,267,296–299]. *T. pallidum* DNA has been detected by PCR in body fluids such as amniotic fluid and infant blood, CSF, and endotracheal aspirate [149,267,296]. PCR tests are not yet clinically validated, for now precluding routine use [297,298]. The lack of access to PCR, the time required for the rabbit infectivity test, and the frequent false-negative microscopic results clearly indicate that serologic testing often is necessary.

## INDIRECT, SEROLOGIC IDENTIFICATION

Serologic assays have played a prominent role in the clinical diagnosis of syphilis since the early 1900s [300]. Nontreponemal antibody tests detect a nonspecific immune reaction and consist of the rapid plasma reagin (RPR) and VDRL assays. Serologic tests detect a specific interaction between serum immunoglobulins and surface antigens of *T. pallidum* and are called treponemal antibody tests. Nontreponemal and treponemal tests have their advantages and disadvantages. In most circumstances, both tests need to be employed in conjunction to make the serodiagnosis of infection with syphilis.

Nontreponemal tests for syphilis are believed to detect antibodies to cardiolipin (diphosphatidylglycerol), a component of normal cell membranes in mammalian tissue. The original test as described by Wassermann used syphilitic tissue as complement-fixing antigen to detect the presence of antibody (*reagin*, a term that should not be used anymore because it is easily confused with IgE) that is induced by *T. pallidum*. Extracts of other normal tissue, such as beef heart, had similar properties, and purification and standardization of these materials led to their use as antigen of preparations containing cardiolipin [300]. Diphosphatidylglycerol constitutes only a small proportion of the lipids of *T. pallidum*, and these organisms may be unable to synthesize this substance at all; it is possible that they incorporate it from damaged host tissues [301]. Production of anticardiolipin antibody could reflect an autoimmune host response to a slightly altered or a differently presented cardiolipin. In this context, it is interesting that anticardiolipin antibody reflects ongoing tissue damage, its detection correlating closely with the amount of activity in the early stages of syphilis infection. These observations may explain why patients with autoimmune diseases, such as systemic lupus erythematosus, characteristically have positive nontreponemal test results as well [300].

The currently available nontreponemal tests, RPR and the automated reagin test, and VDRL slide test, use purified cardiolipin in lecithin-cholesterol liposomes. The nontreponemal tests measure IgG and IgM antibodies [141,302,303]. RPR is positive in approximately 85% of cases of primary syphilis and in 98% of cases of secondary syphilis. VDRL is positive in approximately 80% of primary cases and in 95% of secondary cases (Table 16–3). VDRL is the only serologic assay approved for testing reactivity of spinal fluid [140,279]. RPR and VDRL

**TABLE 16–3** Seroreactivity of Common Tests for Untreated Syphilis

| | % Positive | | | |
|---|---|---|---|---|
| **Test** | **Primary Stage** | **Secondary Stage** | **Latent Stage** | **Tertiary Stage** |
| VDRL or RPR | 80-85 | 95-98 | 75 | <66 |
| FTA-ABS, TP-PA | 75-85 | 100 | 100 | 100 |

*FTA-ABS, fluorescent treponemal antibody, absorbed with non-T. pallidum treponemes; RPR, rapid plasma reagin; TP-PA, T. pallidum particle agglutination; VDRL, Venereal Disease Research Laboratory.*

results are reported as dilutions or titers so that a relative degree of reactivity can be determined. Changes of two dilutions (e.g., a fourfold change from 1:2 to 1:8) are considered significant when assessing disease activity. The RPR titer is often one to two dilutions higher than that obtained using VDRL, so caution must be exercised when comparing results [78].

These quantitative titers help define disease activity and monitor response to therapy: A fourfold decrease suggests adequate therapy, whereas a fourfold increase indicates active disease (treatment failure or reinfection). The quantitative nontreponemal test usually decreases fourfold within 6 months after adequate therapy for primary or secondary syphilis and usually becomes nonreactive within 1 year after successful therapy if the infection was treated during the early stages (primary or secondary syphilis). The patient usually becomes seronegative within 2 years even if the initial titer was high or the infection was congenital [78,304,305]. Even without treatment, the VDRL titer slowly declines and is negative in one third of patients with late syphilis [140]. A few patients remain serofast, with persisting low positive titers despite receiving adequate therapy. This serofast state is more common in patients treated for latent or tertiary syphilis. When nontreponemal tests are used to monitor treatment response, the same specific test (e.g., VDRL or RPR or automated reagin test) must be used throughout the follow-up period, preferably by the same laboratory, to ensure comparability of results [198].

These tests occasionally produce positive results in patients for whom there is no evidence of syphilitic infection, called *biologic false-positive* (BFP); this term is meant to distinguish BFP results from positive reactions owing to technical errors (e.g., Wharton jelly contamination in cord blood specimens leads to technical false-positive reactions) [279,306]. Nontreponemal antibody cross-reacts with more than 200 non–*T. pallidum* spirochetal antigens (although not with the agents of Lyme disease) and can produce false-positive results. Usually, BFP test results have titers less than 1:8 and negative confirmatory test, but they are reported with a frequency of 1% to 20% [198,300,307]. They are classified as either acute (<6 months) or chronic BFP results. Acute BFP reactions can be associated with other infections (e.g., Epstein-Barr virus, varicella, measles, malaria, tuberculosis, brucellosis, mumps, lymphogranuloma venereum, and hepatitis). Chronic BFP reactions are often associated with old age, autoimmune diseases and chronic inflammatory processes (e.g., systemic lupus erythematosus, polyarteritis nodosa, antiphospholipid syndrome, chronic liver disease, endocarditis), malignancy (especially if associated with production of excess IgM), and, rarely, with pregnancy itself [198,300,304,307–313]. Among HIV-positive patients, 10% to 30% have false-positive nonspecific reactions [314]. The antibody detected by VDRL in chronic BFP reactions predominantly is IgM, whereas in syphilis it is mainly IgG; patients with chronic BFP reactions and systemic lupus erythematosus commonly also have a reactive fluorescent treponemal antibody absorption (FTA-ABS) test (see subsequently).

False-negative results can occur when a high concentration of antibody inhibits agglutination (the prozone phenomenon), which can be avoided with serial dilutions of the serum; this occurs in approximately 1% to 2% of individuals, usually with secondary syphilis [247,315,316]. Failure to recognize a prozone effect in maternal serum tested during pregnancy has resulted in failure to diagnose congenital syphilis [247]. Nontreponemal test results may also be falsely negative (i.e., nonreactive) in early (prechancre state) primary syphilis, latent acquired syphilis of long duration, and late congenital syphilis because over the course of time even some untreated patients may revert to seronegative nontreponemal status [198,317–319]. Nontreponemal tests are used primarily for screening (i.e., to establish a "presumptive" diagnosis) and monitoring of therapy [320]. In most instances, a nontreponemal positive reaction is followed up with a treponeme-specific test for confirmation.

## Treponeme-Specific Serologic Tests

Infection with *T. pallidum* causes the host to produce antitreponemal antibodies, which are detected by specific assays, including FTA-ABS and treponeme-specific microhemagglutination test (microhemagglutination–*T. pallidum* [MHA-TP]), now replaced by *T. pallidum* particle agglutination test (TP-PA). FTA-ABS and TP-PA tests measure IgG and IgM antibodies directed against lyophilized Nichols strain antigen. For FTA-ABS, antigen is fixed on a slide, the patient's serum is allowed to react with antigen, and the bound antibody is detected with fluorescently labeled antihuman immunoglobulin antibody, identified by fluorescent microscopy. Test sera are usually preabsorbed with extracts from nonpathogenic *Treponema phagedenis* to eliminate group-reactive antibody, rendering FTA-ABS relatively specific for disease with virulent treponemal species. FTA-ABS is expensive, is time-consuming, and requires a fluorescence microscope and a highly trained technician. It is recommended only for confirmation of positive nontreponemal tests and the diagnosis of later stages of syphilis in which the results of nontreponemal tests may be negative.

Microhemagglutination tests, specifically TP-PA, depend on the passive hemagglutination of erythrocytes or latex particles that have been coated with Nichols strain *T. pallidum* antigen. These tests have been automated, are easy to perform, and are relatively inexpensive. They have largely replaced FTA-ABS [145,305,313,321–327]. MHA-TP is no longer commercially available. TP-PA uses the same treponemal antigen as MHA-TP, but uses gelatin particles rather than sheep red blood cells, which eliminates some nonspecific reactions [328]. Both of the treponeme-specific tests are positive in 75% (TP-PA) to 85% (FTA-ABS) of patients with primary syphilis and in 100% of patients with secondary syphilis (see Table 16–3).* In contrast to nontreponemal tests, titers of the treponemal tests are irrelevant because they do not correlate with disease activity.

False-positive results of specific treponemal tests rarely occur, but may occur in patients with other spirochetal diseases, including Lyme disease, leptospirosis, rat-bite fever, relapsing fever, and diseases caused by other

*References 145, 305, 313, 321, 323–327, 329, 330.

pathogenic *Treponema* species (e.g., yaws, pinta) [121]. A few disease states, such as systemic lupus erythematosus, polyarteritis, or related conditions, and, in one report, even pregnancy are said to cause a false-positive FTA-ABS result [308]. Nontreponemal tests can be used to differentiate Lyme disease from syphilis because VDRL is nonreactive in Lyme disease. Treponemal specific tests are unlikely to revert to a nonreactive state after treatment of the patient, unless treatment was given very early. In one study, however, 24% of patients with a first episode of primary syphilis exhibited a nonreactive result on FTA-ABS testing, and 13% had a nonreactive result on MHA-TP testing at 36 months after treatment [331]. Positive nontreponemal reactions are not helpful in determining whether active infection is present, but a negative result excludes a diagnosis of all but early primary infection and the rare subject who converted back to a serologically negative state.

### Other Serologic Tests

Specific treponemal IgM tests have been developed and have shown great promise in small studies. In contrast to IgG, IgM does not cross the placenta, and detection of specific IgM in an infant would be a strong indication of infection. At this time, these tests are not yet commercially available [121]. Efforts to produce a more sensitive and more specific test are ongoing (e.g., using recombinant *T. pallidum* antigens) [149,332,333]. Some clinical laboratories and blood banks are using treponemal enzyme immunoassay tests [333–339] as initial screening tests. Such reactive screening tests need to be confirmed with another treponemal test different from the one used for screening, such as TP-HA if an enzyme immunoassay is used for screening, and a quantitative test to assess disease activity (RPR or VDRL). These treponemal enzyme immunoassays have advantages such as automation, lack of prozone phenomena, and increased sensitivity in late stages of disease [340–342].

Several developments in diagnostic tests for syphilis promise to make screening and diagnosis of syphilis infection in pregnant women easier for antenatal clinics, particularly in developing countries. The WHO Sexually Transmitted Diseases Diagnostics Initiative (SDI) developed the *ASSURED* criteria as a benchmark to determine whether tests address disease control needs: *a*ffordable, *s*ensitive, *s*pecific, *u*ser-friendly, *r*apid and robust, *e*quipment-free, and *d*eliverable to end-users [111]. Numerous rapid, low-cost specific antibody detection tests based on immunochromatography or latex particle agglutination have already been developed [336,343]. New RPR reagents that are stable at room temperature and simple, rapid treponemal tests that do not require electricity or other equipment are now available with sensitivities, specificities, and costs similar to TP-PA. Some of them require only a finger-prick for venous blood, can use whole blood, do not require refrigeration, and take only 10 to 15 minutes before they can be read. A field trial in Mozambique found that the diagnostic accuracy of some of these newer tests compared favorably with RPR and standards consisting of TP-HA, RPR, and direct immunofluorescence stain undertaken in a reference laboratory [111]. The tests that have been evaluated and found to have acceptable performance characteristics are likely to have a significant impact on the control of syphilis globally [288,344].

Nontreponemal antibody tests (VDRL and RPR and automated reagin test) are best used for screening, and treponemal tests (FTA-ABS and TP-PA) are useful to establish the diagnosis. Nontreponemal antibody tests are also useful in assessing the adequacy of therapy and in detecting reinfection and relapse.

### Cerebrospinal Fluid Tests

For evaluation of possible neurosyphilis, VDRL should be performed on CSF. In addition to VDRL testing of CSF, evaluation of CSF protein and WBC count is used to assess the likelihood of CNS involvement [345]. FTA-ABS testing of CSF is less specific than VDRL, but some experts recommend using FTA-ABS, believing it to be more sensitive. Fewer data exist for TP-PA for CSF, and none exist for RPR; these two tests should not be used for CSF evaluation. Only VDRL is recommended by the CDC for use in CSF evaluation [346–348]. Results from VDRL should be interpreted cautiously because a negative result on VDRL of CSF does not exclude a diagnosis of neurosyphilis. As in evaluating a patient for neurosyphilis, a CSF specimen without contamination by peripheral blood is needed [349].

## APPROACH TO DIAGNOSIS OF ACQUIRED SYPHILIS IN PREGNANCY

All women should be screened serologically for syphilis early in pregnancy with a nontreponemal test (e.g., VDRL or RPR) and preferably again at delivery. In areas of high prevalence of syphilis and in patients considered at high risk of syphilis, nontreponemal serum testing at the beginning of the third trimester (28 weeks of gestation) and at delivery is also indicated [78,175,350,351]. RPR is most commonly used to screen pregnant women for possible infection with *T. pallidum* [224,352].

A definitive laboratory diagnosis of syphilis in pregnancy can be made when the presence of *T. pallidum* is confirmed by direct tests of clinical specimens. A probable or presumptive diagnosis of syphilis can be made when (1) specific or nonspecific serologic tests are reactive in the presence of clinical findings compatible with syphilis, (2) CSF is reactive by VDRL testing, or (3) a specific treponemal antibody test is reactive [78]. Specific treponemal serologic tests should be used to confirm diagnoses suspected on the basis of clinical findings or positive nontreponemal tests. Use of only one type of serologic test is insufficient for a probable diagnosis because false-positive nontreponemal test results occur with various medical conditions, and false-positive treponemal test results occur with other spirochetal diseases (see earlier). Low-titer false-positive nontreponemal antibody test results occasionally occur even in pregnancy. When a pregnant woman has a reactive nontreponemal test result and a persistently negative treponemal test result, a false-positive test result is confirmed. The probability of syphilis is high in a sexually active pregnant woman whose serum is newly

reactive on nontreponemal and treponemal tests, whether the woman is symptomatic or not. Some laboratories now screen pregnant women using an enzyme immunoassay treponemal test; pregnant women with reactive treponemal screening tests should have confirmatory testing with a nontreponemal test with quantitative titers.

Differentiating syphilis treated in the past from reinfection often is difficult unless the nontreponemal titer is increasing. For women who tested positive and were treated during pregnancy, follow-up serologic testing is necessary to assess the efficacy of therapy. A woman who had been adequately treated with penicillin and followed with quantitative serologic testing and who has no evidence of reinfection does not need retreatment with each subsequent pregnancy. One third of congenital syphilis infections seem to be due to repeat infections [353], however, indicating that any pregnant woman with syphilis, past or present, should be reevaluated carefully, and if any doubt exists about the adequacy of previous treatment or the presence of active infection or risk for reinfection, a course of treatment should be given to prevent congenital syphilis. All pregnant women who have syphilis should also be tested for other sexually transmitted diseases, including HIV infection. Any woman who delivers a stillborn infant after 20 weeks' gestation should also be tested for syphilis [78,83].

The above-described approach of serologic screening is a poor diagnostic approach during the incubation or early primary stage of syphilis, and cases of congenital syphilis have occurred in women who were incubating syphilis at the time of delivery (i.e., at a time their screening serologic tests were still negative). During those times, results of nontreponemal (RPR or VDRL) tests may not show reactivity because reactivity occurs 4 to 8 weeks after the infection is acquired and several days to 1 week after the development of a chancre [309]. In primary syphilis during pregnancy, nonreactivity on nontreponemal testing is reported to occur in one fourth to one third of cases [247,316]. Nonreactivity on the specific TP-PA and FTA test occurs in 36% and 18% of cases of primary syphilis [300]. The clinician caring for a pregnant woman has to maintain a high level of suspicion in cases of a sexually active pregnant woman. Detection of the spirochete from active lesions is the only means to establish the diagnosis in this scenario; this requires careful physical examination at multiple time points during pregnancy [78].

Usually, HIV infection in women does not alter serology, but atypical results must be expected [198]. Frequent false-negative serology in primary and secondary syphilis [354,355], prozone phenomenon [356], serofast reactions [357], and specific antibodies becoming negative after therapy [358] all have been reported. False-positive nonspecific reactions are observed in 11% of patients [359]. Sometimes there is a false-negative FTA-ABS test. A delayed decline in titer can occur and apparently is of no clinical relevance. Despite such varying serologic responses, work-up for syphilis in HIV-infected women should not be different from that of HIV-negative cases [354]. However, the possibility of negative serology in early syphilis must be considered, and detection of the pathogen must be attempted in such cases [73].

## APPROACH TO DIAGNOSIS OF CONGENITAL SYPHILIS

Several diagnostic categories for congenital syphilis have been proposed, and minor differences among case definitions formulated by several agencies and experts still exist [78,89,360,361]. In Table 16–4, we have attempted to reconcile several of these diagnostic categories with the CDC guidelines from 2006. A *definitive* diagnosis of congenital syphilis can be made in the rare situation in which the organism can be identified directly in the infant. A *highly probable* diagnosis is suggested if there are clinical findings consistent with congenital syphilis (see Tables 16–1 and 16–2), if the infant has a fourfold higher nontreponemal serologic titer than the mother, or if the infant has a positive CSF VDRL result. The diagnostic category of *probable* describes clinically asymptomatic infants who have a nontreponemal serologic titer that is equal to or less than that of the mother, but where maternal treatment did not occur at all, was inadequate, was not documented, or failed (i.e., did not lead to a sufficient decline in maternal nontreponemal titers).

The diagnosis of *possible* congenital syphilis is made when the nontreponemal serologic test result of an asymptomatic infant is reactive, but equal to or less than that of the mother who did receive adequate treatment either during or before this pregnancy. The diagnosis of congenital syphilis is *unlikely* if the nontreponemal serologic test result of an asymptomatic infant born to an

**Mother was not treated, inadequately treated (i.e., was treated with a nonpenicillin regimen, or was treated <30 days before delivery, or titers did not fall appropriately), or has no documentation of having received treatment.*

*CDC, Centers for Disease Control and Prevention; PCR, polymerase chain reaction; RIT, rabbit infectivity test; RPR, rapid plasma reagin (test); STS, serologic test for syphilis; VDRL, Venereal Disease Research Laboratory (test).*

*Modified from Centers for Disease Control and Prevention. Available at http://www.cdc.gov/std/treatment/2006/congenital-syphilis.htm. Accessed January 21 2008.*

adequately treated mother is nonreactive. The "unlikely" label does not exclude the possibility of congenital infection, however, in cases where the mother is seronegative at the time of testing because she is in the incubation period of early syphilis [78,101,242,362–365]. Given the difficulty of diagnosis and the severity of untreated congenital syphilis, the "evaluate and treat when uncertain" approach to congenital syphilis is the most prudent (see "Therapy").

Overall, the decision to evaluate and ultimately to treat an infant for congenital syphilis is largely based on clinical, serologic, and epidemiologic considerations. The evaluation includes an assessment of the mother for general risk factors, followed by an evaluation of the mother's current known serologic status. No newborn infant should be discharged from the hospital without determination of the mother's serologic status for syphilis, regardless of whether the mother and the infant are asymptomatic [366]. Cord blood should not be tested because it frequently yields false-positive or false-negative results, and tests of postnatal infant serum can be nonreactive if maternal titers are low or the mother was infected late in pregnancy. Conversely, transplacental transmission of nontreponemal and treponemal antibodies to the fetus can occur in a mother who has been treated appropriately for syphilis during pregnancy, resulting in positive test results in the uninfected newborn infant (the neonate's nontreponemal test titer in these circumstances usually reverts to negative in 4 to 6 months, whereas a positive FTA-ABS or TP-PA result from passively acquired antibody may not become negative for $\geq$1 year).

Taking the aforementioned considerations together, the optimal starting point for the serologic evaluation of a suspected case of congenital syphilis is maternal serum [78,179,275]. An infant's serologic titer often is one to two dilutions less than that of the mother's titer; an infant may have a nonreactive umbilical cord VDRL, but have a mother with a reactive serologic test for syphilis at delivery. From 1987–1990, Sanchez and coworkers [362] compared results of maternal serologic studies at delivery with results obtained from VDRL testing of umbilical cord blood and documented 534 cases with reactive maternal serologic tests at delivery, but negative umbilical cord blood VDRL results. Of these infants, 87 (16%) were born to mothers with untreated syphilis at delivery and were at risk for infection if treatment were not given. These infants would not have been identified if only the umbilical cord blood had been screened. When the only evidence of congenital syphilis is a newly positive maternal nontreponemal test, the maternal diagnosis should be confirmed with a treponemal test before an otherwise well, asymptomatic infant undergoes further evaluation and treatment for congenital syphilis, unless the wait for results would unduly delay providing appropriate care for the infant, or there is significant risk for loss to follow-up [83,121].

All infants born to seropositive mothers require a careful examination and a quantitative nontreponemal syphilis test. The test performed on the infant should be the same as the test performed on the mother to enable comparison of titer results. It is generally agreed that an infant should be evaluated further for congenital syphilis if the maternal titer has increased fourfold, if the infant titer is fourfold greater than the mother's titer, or if the infant has clinical manifestations of syphilis [149]. Infant nontreponemal titers fourfold higher than maternal titers are uncommon even in symptomatic cases, however, and infant-to-mother ratios less than fourfold do not exclude congenital infection. High nontreponemal titers at the time of maternal treatment during pregnancy and at delivery and gestational age less than 37 weeks at delivery are risk factors for the acquisition of congenital syphilis in the neonate even when maternal treatment was adequate [367].

Assessment of maternal treatment for syphilis, in terms of the regimen used, timing of therapy relative to delivery (<30 days versus $\geq$30 days), and maternal follow-up and results of serial nontreponemal antibody titers, is key in determining the extent of evaluation and treatment needed for an infant at risk for congenital syphilis. The only maternal treatment considered effective (see "Therapy") is benzathine penicillin G, 2.4 million U intramuscularly; a single dose is deemed sufficient when the mother has primary, secondary, or early latent syphilis. Three doses administered at 1-week intervals are required for late latent or tertiary syphilis [78,121].

Infants born to women who have had syphilis in the past, received therapy, and remained seroreactive also are seroreactive. Ensuring that such an infant does not have congenital disease in the immediate newborn period may be impossible. If the infant's reactive RPR is caused by passively transferred antibody from a previously infected mother, the reactivity in the infant progressively declines as time passes and should disappear by 6 months of age. A persistently reactive RPR in the infant beyond 12 to 15 months of age suggests an active infection, and an increasing titer makes this diagnosis certain [279,368]. Infants who have (1) normal physical findings *and* (2) a serum quantitative nontreponemal antibody titer that is fourfold or less than the maternal titer do not require further laboratory or clinical evaluation *if* (1) maternal treatment adequate for the stage of syphilis was administered more than 4 weeks before delivery (including before pregnancy), *and* either (2a) the mother had early syphilis at the time of treatment and her nontreponemal titers decreased at least fourfold and have remained low and stable through the time of delivery, or (2b) the mother had late syphilis at the time of treatment, her nontreponemal titers have remained low and stable, and there is no evidence of relapse and no risk for reinfection [121,352].

If these requirements are not completely met, or even the slightest doubt exists, evaluation for syphilis in an infant should occur and include the following: [50,83]

1. Physical examination.
2. A quantitative nontreponemal serologic test for syphilis using serum from the infant (not cord blood because false-positive and false-negative results can occur). A specific treponemal test such as FTA-ABS is unnecessary in the newborn period if the mother is known to have a reactive result.
3. Long bone radiographs, unless the diagnosis has been established otherwise. Long bone radiographs are one of the most sensitive clinical studies for detection of physical evidence of congenital

syphilis in otherwise asymptomatic infants [369]. They are abnormal in approximately 65% of infants with clinical findings of syphilis, but only in a few asymptomatic infants (i.e., if osteochondritis or periostitis is found in an infant born to a mother with a reactive serologic test for syphilis, this is indicative of congenital syphilis, and the infant requires a full course of intravenous penicillin therapy). The value of long bone radiographs and CSF examinations in the diagnosis of congenital syphilis has been questioned during a time when syphilis was of low prevalence in the study population [370,371], but the recommendations for long bone radiographs and CSF VDRL determinations are based on their sensitivity and specificity from previous epidemics [369] and are most relevant today.

4. Complete blood cell count including hematocrit and hemoglobin, red blood cell count, reticulocyte count, platelet count, WBC count with differential, and direct Coombs test.
5. Other clinically indicated tests (e.g., chest radiograph, liver function tests, cranial ultrasound, ophthalmologic examination, and auditory brainstem response).
6. Pathologic examination of the placenta or umbilical cord using specific fluorescent antitreponemal antibody staining.
7. VDRL of CSF and analysis of CSF for cells and protein concentration (specific indications are explained subsequently).

CSF should be examined in an infant who is evaluated for congenital syphilis if the infant has any of the following: (1) abnormal physical examination findings consistent with congenital syphilis, (2) a serum quantitative nontreponemal titer that is fourfold greater than the mother's titer, or (3) positive dark-field microscopy or fluorescent antibody test result on body fluid [78,83,149,372]. Infants with these findings are considered to have proven disease, and spirochetemia with invasion of the CNS occurs in approximately 40% to 50% of these infants, so they must receive a full 10-day course of intravenous penicillin therapy [149,267]. Leukocytosis ($\geq$25 WBCs/mm$^3$) and elevated protein content (>150 mg/dL in full-term infants and >170 mg/dL in preterm infants) in the CSF in an infant who exhibits any features suggestive of congenital syphilis should be regarded as supportive of the diagnosis. Also, an infant with reactive CSF on VDRL testing should receive presumptive treatment for neurosyphilis [345].

Specific treponemal tests should not be done using CSF in infants suspected to have congenital syphilis because the results cannot be interpreted properly [346–348]. Given that the diagnosis of congenital neurosyphilis is difficult to establish without a positive direct test, and because findings such as the presence of red blood cells in the CSF owing to a traumatic lumbar puncture can produce a false-positive serologic reaction, and other markers in the CSF of newborns and infants (CSF WBC counts and protein concentrations) vary widely as well, it is generally agreed that any infant with proven or probable congenital syphilis requires 10 days of parenteral treatment with penicillin G regardless of CSF test results [78,83]. The problem of unequivocally identifying an infected infant underscores the need for an "evaluate and treat when uncertain" approach to congenital syphilis in general and to congenital neurosyphilis in particular. Given this paradigm, although a complete evaluation is preferred for optimal planning of care, it may be unnecessary if a full 10-day course of parenteral penicillin is provided because such therapy would treat congenital CNS infection [369,370].

In settings with poor resources, the major difficulties in making a diagnosis of congenital syphilis are identifying the potentially large number of infants who have congenital syphilis as their mother's infection has remained undetected during pregnancy and confirming clinical suspicion without sophisticated laboratory tests. In these situations, confirmation of clinical suspicion is restricted to VDRL or RPR. The results in the mother and infant using the same test should be compared, and a fourfold higher titer in the infant should be accepted as probable infection. The value of performing a lumbar puncture or bone radiographs in asymptomatic infants in settings with poor resources in an attempt to confirm the diagnosis is of questionable value. In instances where infection is probable or suspected, the infant should be treated for congenital syphilis with a full 10-day course of intravenous penicillin G [111].

## DIFFERENTIAL DIAGNOSIS

The typical findings of congenital syphilis, such as snuffles, vesiculobullous eruption, hepatosplenomegaly, generalized lymphadenopathy, and symmetric bony lesions, closely resemble features of other diseases in neonates that are unrelated to syphilis. The numerous neonatal conditions that have to be considered in the differential diagnosis include congenital infections caused by cytomegalovirus, *Toxoplasma gondii*, herpes simplex virus, rubella virus, and bacterial sepsis; blood group incompatibility; battered child syndrome; and periostitis of prematurity. Most findings in syphilis are due to the inflammatory reaction to a widely disseminated pathogen, and this pathogenesis unites many of the above-listed entities [121,373–375].

## DERMATOLOGIC MANIFESTATIONS

The vesiculobullous manifestations of congenital syphilis may be confused with other infections or with congenital disorders of the skin that can manifest as vesiculobullous eruptions [376]. Infection caused by *Staphylococcus aureus* can produce vesicles or bullae on any part of the body. Severe infection may result in confluent bullae with erythema and desquamation (Ritter's disease). Examination of aspirated fluid reveals many polymorphonuclear leukocytes and occasionally gram-positive cocci in clusters, and culture yields the organism. *Pseudomonas aeruginosa* septicemia can be accompanied by a cutaneous eruption consisting of clustered pearly vesicles on an erythematous background, which rapidly becomes purulent green or hemorrhagic [377]. When the lesion ruptures, a circumscribed ulcer with a necrotic base appears and may persist, surrounded by a purplish cellulitis. Culture of the lesion and the blood confirms the diagnosis. In the septicemic

early-onset form of listeriosis, a cutaneous eruption consisting of miliary lesions resembling papules, pustules, or papulopustules can occur over the entire body, with a predilection for the back [378]. Culture of these lesions and blood usually reveals *Listeria monocytogenes* as the etiologic agent. Additional infectious causes of vesicular or bullous lesions of the skin of the newborn include group B streptococci [379], *Haemophilus influenzae* type b [380], *Mycobacterium tuberculosis* [381], and cytomegalovirus [382].

In virus-induced eruptions, the vesicles are located in the mid-epidermis. In herpesvirus infection, vesicles are the most common dermatologic manifestation. They tend to be sparsely disseminated throughout the body, or they may occur in crops or clusters. Involvement of the palms and soles has been recorded, as has the formation of bullae. Recurrence of these skin lesions is not unusual. Culture, fluorescent staining, or PCR on scrapings from the base of these lesions reveals herpes simplex virus. Varicella-zoster infection seems to have a similar pattern, but rarely occurs in the newborn period, and the diagnosis may be discarded on epidemiologic or clinical grounds. Variola and vaccinia can affect the fetus or newborn and cause vesicular eruptions. Appropriate epidemiologic evidence should be sought to exclude these diagnoses.

Mucocutaneous candidiasis may manifest as a vesicular dermatitis at the end of the 1st week of life. The vesicles usually become confluent and rupture, leaving a denuded area surrounded by satellite vesicles or pustules. Congenital candidiasis with skin manifestations also has been described, and severe systemic involvement may accompany this intrauterine infection [383].

Various hereditary disorders of the skin appear at birth or in early infancy as vesiculobullous eruptions [376]. Epidermolysis bullosa is a group of specific genetic disorders. Erythema toxicum, miliaria rubra, incontinentia pigmenti, urticaria pigmentosa, epidermolytic hyperkeratosis, acrodermatitis enteropathica, Langerhans cell histiocytosis (histiocytosis X), transient neonatal pustular melanosis, infantile acropustulosis, and aplasia cutis congenita all should be included in the differential diagnosis [376].

## SNUFFLES

Increased neonatal nasal discharge is a common phenomenon, but has not been well studied. It is described as mucoid rhinorrhea with nasal mucosal edema in an afebrile newborn that results in stertor, poor feeding, and respiratory distress. The etiology is most often not identified, but it is presumed to be allergic in nature. The recognition and treatment of this condition is important because neonates are obligate nasal breathers. A diagnostic-therapeutic trial consisting of conservative therapy (suctioning) and corticosteroid is recommended. An important alternative consideration not to be missed is infection with *Chlamydia trachomatis*, but this entity should be recognized by the associated clinical findings [387].

## LYMPHADENOPATHY

Lymph node size varies with age and the location, but in neonates, lymph nodes are normally barely palpable. Localized lymphadenopathy can be found in one third of neonates and infants, usually in nodes that drain areas with skin irritation or localized infections. Generalized adenopathy is rare in the neonate and if present can be seen with other congenital infections such as cytomegalovirus [384].

## HEPATOSPLENOMEGALY

When the clinical presentation includes hepatosplenomegaly with or without jaundice, the list of possibilities in the differential diagnosis is extensive and includes all causes of elevated direct and indirect bilirubin. The physician should consider isoimmunization (e.g., Rh incompatibility, ABO incompatibility); other infectious diseases, such as early-onset sepsis, cytomegalovirus infection congenital rubella, herpes simplex infection, coxsackievirus B or other enteroviral infections, and toxoplasmosis; neonatal hepatitis; diseases of the biliary tract (e.g., extrahepatic biliary atresia, choledochal cyst); and genetic and metabolic disorders (e.g., cystic fibrosis, galactosemia, $\alpha_1$-antitrypsin deficiency) [384].

## HYDROPS FETALIS

Hydrops fetalis can be caused by chronic anemia (isoimmunization disorder, homozygous $\alpha$-thalassemia, fetal-maternal or fetal-fetal transfusions); cardiac or pulmonary failure from causes other than anemia (large arteriovenous malformations, premature closure of the foramen ovale, cystic adenomatoid malformation, pulmonary lymphangiectasia); perinatal tumors (neuroblastoma, chorioangioma); achondroplasia; renal disorders (congenital nephrosis, renal vein thrombosis); and infections, such as congenital cytomegalovirus infection, toxoplasmosis, parvovirus B19 infection [385], and congenital hepatitis [384]. Most cases of hydrops are caused by isoimmunization disorders, which can be excluded as a cause by a negative direct Coombs test result. A normal hemoglobin electrophoresis pattern excludes the diagnosis of $\alpha$-thalassemia. The Kleihauer-Betke technique of acid elution for identifying fetal cells in the maternal circulation can aid in ruling out the diagnosis of fetal-maternal transfusion. Other diagnostic considerations can be discarded on the basis of appropriate radiographic studies, placental examination, urinalysis with microscopy, biopsy, and immunologic studies [384].

## RENAL DISEASE

In neonates and young infants, nephrotic syndrome and acute nephritis occur infrequently. The former more often is associated with infantile microcystic disease, minimal-lesion nephrotic syndrome, or renal vein thrombosis than with congenital syphilis [384]. Neonatal nephritis can occur as a manifestation of congenital syphilis, hereditary nephritis, hemolytic-uremic syndrome, and, rarely, pyelonephritis. The clinical signs that distinguish syphilitic renal involvement from the other conditions mentioned include the presence of other manifestations of early congenital syphilis, a positive result on serologic tests for syphilis, elevated levels of IgG (in infantile microcystic disease, the levels of IgG are low), and the response to specific therapy for syphilis [279].

## OPHTHALMOLOGIC INVOLVEMENT

Neonatal glaucoma, an uncommon finding in syphilis, occurs as an isolated genetic disorder and may be associated with various syndromes, such as aniridia, Hallermann-Streiff syndrome, Rieger anomaly, Lowe syndrome, Sturge-Weber syndrome, oculodentodigital syndrome, and Pierre Robin syndrome; it also is associated with congenital rubella [386]. Nasolacrimal duct obstruction is a more frequent cause of excessive lacrimation in the newborn period and early infancy.

## BONY INVOLVEMENT

Periostitis of congenital syphilis usually occurs during the early months of life and must be distinguished from periostitis seen in healing rickets, battered child syndrome, infantile cortical hyperostosis, various poorly understood disorders presumed to be related to nutritional deficiencies, occasionally pyogenic osteomyelitis [187], and prostaglandin-induced periostitis [387]. Although Wimberger sign formerly was thought to be pathognomonic of congenital syphilis, it has been described in other disease states, including osteomyelitis, hyperparathyroidism, and infantile generalized fibromatosis [234]. The "celery stick" appearance of alternating bands of longitudinal translucency and relative density is a finding also seen in congenital rubella and cytomegalovirus infection [187].

# THERAPY

Early treatments for syphilis included mercury (first used in 1497), arsphenamine, other heavy metals, and malaria inoculation for paretic cases [388]. The breakthrough in treatment came in 1943 when Mahoney [389] successfully used penicillin to treat primary syphilis in four patients. Parenteral penicillin has since remained the preferred drug for treatment of syphilis at any stage [50]. Recommendations for specific types of penicillin and duration of therapy vary, depending on the stage of disease and clinical manifestations. However, parenteral penicillin G is the only documented effective therapy for patients who have neurosyphilis, congenital syphilis, or syphilis during pregnancy and is recommended for HIV-infected patients. Such patients always should be treated with penicillin, even if desensitization for penicillin allergy is necessary [50,390]. Penicillin resistance has not been described in *T. pallidum*, which is exquisitely sensitive with a penicillin minimal inhibitory concentration of 0.004 U (or 0.0025 μg/mL) [391–393]. Effective therapy for syphilis has to be maintained for at least 7 to 10 days, however, because of the slow replication of *T. pallidum* (every 30 hours) [394]. Therapy is designed to achieve and maintain several times the necessary inhibitory levels [50].

## TREATMENT OF ACQUIRED SYPHILIS IN PREGNANCY

A serologic test for syphilis should be performed on all pregnant women at the first prenatal visit or not later than the time a pregnancy is confirmed [50]. Pregnant women with any reactive serologic tests for syphilis should be considered infected unless an adequate treatment history is documented and sequential nontreponemal antibody titers have declined [78,372]. A pregnant woman with a negative RPR screening test should still receive immediate therapy if the following conditions are present: (1) She has a suspicious lesion, and a negative RPR result may reflect the early stage of her infection; detection of treponemes by dark-field microscope should lead to therapy without regard to results of serologic tests; RPR should be repeated in 3 to 6 weeks in all of these cases. (2) She has neither lesions nor positive results of serologic studies, but has been exposed sexually to a person who has or may have syphilis; in this case she should receive treatment for the chance that she has acquired syphilis and is in the early phase of the infection and might transmit infection to her fetus [242,362].

Regardless of the stage of pregnancy, patients should be treated with penicillin according to the dosage schedules appropriate for the stage of syphilis [50,287]. Early syphilis—primary, secondary, and early latent infection—is treated with benzathine penicillin G, 50,000 U/kg up to the maximal dose of 2.4 million U intramuscularly in a single dose [50,394–396]. Many experts recommend that an additional dose of benzathine penicillin G be provided 1 week after the initial dose [50]. Late latent syphilis requires benzathine penicillin administered as 50,000 U/kg up to the adult dose of 2.4 million U at 1-week intervals for 3 consecutive weeks (i.e., total combined dose of 150,000 U/kg up to the maximal dose of 7.2 million U), but only if the CSF examination has excluded neurosyphilis. When the duration of infection is unknown, the patient should be treated as for late latent disease. Management and treatment decisions may be guided further by the use of fetal ultrasonography. Evidence of fetal infection may require additional doses of benzathine penicillin G until resolution of fetal abnormalities can be documented [279].

A pregnant woman with a history of penicillin allergy should be treated with penicillin after desensitization (see subsequently for instructions) because no proven alternative therapy has been established. In some patients, skin testing may be helpful. In pregnant women, desensitization should be performed in consultation with a specialist and only in facilities in which emergency assistance is available [397]. Pregnant women who received therapy for gonorrhea with ceftriaxone have a high rate of cure of primary syphilis, but failures have occurred, and efficacy in pregnancy is not well studied [398]. This regimen cannot be assumed to provide adequate therapy for syphilis in pregnancy. Any therapy other than penicillin is considered to be inadequate therapy during pregnancy [65,399]. Nonetheless, failure rates of penicillin for prevention of fetal infection ranging from 2% to 14% have been reported [400]. Most fetal treatment failures seem to occur after maternal treatment for secondary syphilis [401]. Treatment failure in such cases may be explained partly by the marked spirochetemia that occurs during secondary syphilitic infection. Other reasons for the presumptive treatment failures have been related to possibly altered penicillin pharmacokinetics in pregnancy [402] or to advanced fetal disease [403].

## Neurosyphilis

Invasion of the CNS by *T. pallidum* can occur during any stage of syphilis [80]. During early syphilis, evaluation of CSF in a pregnant adolescent or adult is necessary only if clinical signs or symptoms of neurologic or ophthalmic involvement are present [50,404]. A lumbar puncture in a pregnant adolescent or adult in the late stages of syphilis is indicated if there are findings on neurologic or ophthalmic examination of active tertiary syphilis (e.g., aortitis, gumma), the patient has had previous treatment failure, or the patient was treated with an antimicrobial agent other than penicillin [89]. Some experts also recommend performing a CSF examination on all patients who have latent syphilis and a nontreponemal serologic test result of 1:32 or greater. All HIV-infected pregnant women with late latent syphilis or syphilis of unknown duration should have a lumbar puncture and CSF examined [80,395,405].

Benzathine penicillin does not reliably produce inhibitory CSF levels of penicillin [406], and numerous reports describe the persistence of treponemes in the CSF after therapy for syphilis [57,407–413]. Shorter acting penicillins must be employed for neurosyphilis. The recommended regimen for pregnant adults with neurosyphilis is aqueous crystalline penicillin G, 18 to 24 million U/day, administered as 3 to 4 million U intravenously every 4 hours or continuous infusion for 10 to 14 days. If adherence to therapy can be ensured, patients may be treated with an alternative regimen of intramuscular penicillin G, 2.4 million U intramuscularly once daily, plus probenecid, 500 mg orally four times per day, for 10 to 14 days. Because these regimens are shorter than the regimen used for late latent syphilis, some experts recommend following both of these regimens with benzathine penicillin G, 2.4 million U (or 50,000 U/kg per dose) intramuscularly weekly for one to three doses [78].

## Human Immunodeficiency Virus

For HIV-infected pregnant women with primary or secondary syphilis, some authorities recommend up to three weekly doses of 2.4 million U of benzathine penicillin G in addition to the single intramuscular dose of benzathine penicillin G. HIV-infected patients who have either late latent syphilis or syphilis of unknown duration require a CSF examination before treatment. If nontreponemal antibody titers have not declined fourfold by 6 months in primary or secondary syphilis or by 6 to 12 months in early latent syphilis, or if the titer has increased fourfold at any time, a CSF examination should be performed, and the patient should be retreated with 7.2 million U of benzathine penicillin G (administered as three weekly doses of 2.4 million U each) if CSF examination findings are normal. HIV-infected pregnant patients who have CSF abnormalities consistent with neurosyphilis should receive treatment for neurosyphilis as described earlier [73,78].

## Postexposure Prophylaxis

Recommendations for postexposure prophylaxis for syphilis for exposed or possibly exposed health care providers are benzathine penicillin G, 2.4 million U intramuscularly $\times$ 1 dose or doxycycline, 100 mg orally twice daily $\times$ 2 weeks, as an alternative for nonpregnant health care providers. These recommendations are largely based on guidelines for the epidemiologic treatment of suspected sexual contacts [414–417].

# TREATMENT OF CONGENITAL SYPHILIS

Infants should be treated for congenital syphilis if they have *definite*, *highly probable*, *probable*, or *possible* disease. Infants in the *unlikely* category (for definitions of these terms, see Table 16–4) are recommended to receive therapy, as are infants born to mothers with either clinical or serologic evidence of syphilis infection for whom test results cannot exclude infection, who cannot be evaluated completely, or for whom adequate follow-up cannot be ensured [78,390]. The difference between these categories is only the type of therapy that is recommended. Infants in the *definite* and *highly probable* categories (i.e., clinically symptomatic infants) should be treated with intravenous aqueous crystalline penicillin G for 10 to 14 days at 50,000 U/kg per dose every 12 hours (100,000 U/kg/d) during the first 7 days of life and every 8 hours during days 8 to 30 (150,000 U/kg/d). Intramuscular procaine penicillin G, 50,000 U/kg/d as a single daily dose for 10 to 14 days, has also been proposed by some experts as an alternative [78,369,390]. Adequate CSF concentrations may not be achieved with intramuscular procaine penicillin; if intramuscular procaine penicillin is chosen, an unequivocally negative CSF examination must be available before initiating this form of therapy [418]. A full 10-day course of penicillin is preferred even if the infant received ampicillin initially for possible sepsis. Also, if more than 1 day of therapy is missed, the entire course needs to be restarted [78].

## Clinically Asymptomatic Infants

Treatment decisions of clinically "asymptomatic" infants (i.e., in the probable, possible, or unlikely category) are based on (1) the maternal history of syphilis and past treatment and (2) the infant serologic evaluation. Maternal treatment for syphilis is deemed inadequate if (1) the mother's penicillin dose is unknown, undocumented, or inadequate; (2) the mother received a treatment regimen not including penicillin during pregnancy for syphilis; (3) treatment was given within less than 30 days of the infant's birth; or (4) mother has early syphilis and has a nontreponemal titer that either has not decreased fourfold or has increased fourfold [364,419]. For an asymptomatic infant of a mother with a positive serologic screen, three possible scenarios need to be considered: [78,149,390]

1. If the mother's treatment was inadequate, and an asymptomatic infant's nontreponemal test is reactive, the infant is deemed to have *probable* congenital syphilis [78]. If medical follow-up is certain, the infant may be treated with a single intramuscular dose of benzathine penicillin G, 50,000 U/kg. Single-dose benzathine penicillin therapy has been widely used in the past, and its use allows for earlier hospital discharge of the infant with subsequent improved maternal-infant interaction and decrease in hospitalization costs [420]. This regimen has also

been supported by two small clinical studies [421,422]. If the infant is to receive a single intramuscular injection of benzathine penicillin G, a complete evaluation—including a lumbar puncture—is mandatory [78,279,390,421,422]. Given the difficulty of ruling out neurosyphilis unequivocally, many experts prefer the 10-day intravenous course with aqueous crystalline penicillin G for all infants in this category [267,287,397]. If any part of the evaluation is abnormal, unavailable, or uninterpretable (e.g., CSF contaminated by blood), a full 10- to 14-day regimen is recommended [390]. If the meaning of a positive RPR result in an otherwise normal infant is in doubt, and the results of all other tests are negative, repeat quantitative RPR testing should be undertaken [78,390].

2. If the mother's treatment was adequate, but an asymptomatic infant's nontreponemal serum test is reactive, the infant is said to have *possible* congenital syphilis. Some experts recommend that a single dose of benzathine penicillin be administered as described previously [78,121,390,421,422]. Failure of such therapy in three infants has been reported [406,423,424]. Given these concerns, most experts suggest that all infants with possible congenital syphilis receive parenteral penicillin therapy for 10 days, especially if the mother had secondary syphilis at delivery or seroconverted during the pregnancy [60,170,402].
3. If the mother was treated adequately during the pregnancy, and the serologic assessment is nonreactive in an asymptomatic infant, the infant is *unlikely* to have congenital syphilis. Because of the inability to rule out possible transmission to the fetus in these cases, we recommend a single intramuscular dose of benzathine penicillin even for infants falling into this *unlikely* group. If the choice is made not to treat an infant in this category, close follow-up has to be ensured, and such an infant needs to undergo a second RPR test within 3 to 4 weeks of birth. Finally, the appearance of secondary or tertiary syphilis in a mother within 1 year after delivery should prompt a thorough reevaluation of the infant [242,362].

### Internationally Adopted Children

Congenital syphilis sometimes is undiagnosed and often inadequately treated in developing countries. Syphilis testing is recommended as part of the evaluation of internationally adopted children, regardless of history or report of evaluation and treatment abroad [121,425]. When congenital syphilis of any stage and site is identified beyond the neonatal period, the treatment regimen for acquired neurosyphilis should be used: 200,000 to 300,000 U/kg/d of aqueous crystalline penicillin G, given as 50,000 U/kg every 4 to 6 hours for a minimum of 10 to 14 days. Some experts follow this regimen with intramuscular doses of benzathine penicillin G, 50,000 U/kg weekly for 3 weeks. If the patient has no clinical manifestations of disease, CSF examination is normal, and the result of VDRL of CSF is negative, some experts treat only with three weekly doses of benzathine penicillin G (50,000 U/kg intramuscularly). When intravenous or intramuscular penicillin preparations are unavailable (see later) or cannot be tolerated, intravenous ampicillin or parenteral ceftriaxone can be considered as alternative therapy, but careful clinical and serologic follow-up is essential when these regimens are used because data for efficacy are insufficient [78,121,390].

## FOLLOW-UP FOR A PREGNANT WOMAN INFECTED WITH SYPHILIS

Treated pregnant women with syphilis should have quantitative nontreponemal serologic tests repeated at 28 to 32 weeks of gestation, at delivery, and following the recommendations for the stage of disease. Serologic titers may be repeated monthly in women at high risk of reinfection or in geographic areas where the prevalence of syphilis is high. The clinical and antibody response should be appropriate for stage of disease. In practice, however, most women deliver before their serologic response to treatment can be assessed definitively. All pregnant women with acquired syphilis and all of their recent sexual contacts should be evaluated for syphilis and other sexually transmitted infections. For pregnant HIV-infected women with syphilis, careful follow-up is essential because higher rates of treatment failure have been reported [78,390].

In a pregnant woman with primary or secondary syphilis, retreatment should be considered necessary if clinical signs or symptoms persist or recur, if a fourfold increase in titer of a nontreponemal test occurs (also evaluate CSF and HIV status), or if the nontreponemal titer fails to decrease fourfold within 6 months after therapy (the woman also should be evaluated for HIV and retreated, unless follow-up for continued clinical and serologic assessment can be ensured). In a pregnant woman with latent syphilis, a CSF evaluation should be performed, and the woman should be retreated if titers increase fourfold, if an initially high titer (>1:32) fails to decrease at least fourfold within 12 to 24 months, or if signs or symptoms attributable to syphilis develop at anytime. In all these instances, retreatment should be with three weekly injections of benzathine penicillin G, 2.4 million U intramuscularly, unless CSF examination indicates that neurosyphilis is present, at which time treatment for neurosyphilis should be initiated. Generally, only one retreatment course is indicated. The possibility of reinfection or concurrent HIV infection always should be considered when retreating pregnant patients with syphilis. Pregnant patients with neurosyphilis must have periodic serologic testing, clinical evaluation at 6-month intervals, and repeated CSF examinations. If the CSF cell count has not decreased after 6 months, or CSF is not entirely normal after 2 years of therapy, retreatment should be considered [78,390].

## FOLLOW-UP FOR AN INFANT INFECTED WITH SYPHILIS

Infants should be reevaluated after treatment for definite, probable, or possible congenital syphilis at 1, 2, 3, 6, and 12 months of age [426]. Nontreponemal serologic tests

should be performed 2 to 4, 6, and 12 months (i.e., incorporated into routine pediatric care) after conclusion of treatment, or until results become nonreactive or the titer has decreased fourfold [233,279]. When nontreponemal antibodies are of maternal origin, titers usually become negative within 3 months and should be negative by 6 months of age if the infant was not infected [427]. The serologic response after therapy may decline more slowly for infants treated after the neonatal period.

If the choice was made not to treat an infant in the *unlikely* category, a nontreponemal test has to be performed at 3 to 4 weeks of age; untreated infants who are not seronegative by 6 months of age should be fully reevaluated clinically and treated. If titers of nontreponemal antibodies remain stable or increase after age 6 to 12 months in any infant, he or she should be reevaluated (including CSF analysis) and treated with a 10-day parenteral course of penicillin G, even if the infant had been treated previously [78,390]. Treponeme-specific antibodies of maternal origin may persist for 12 to 15 months in 15% of uninfected infants [428], rendering these tests of little help during infancy. Reactivity at 18 months or beyond is indicative of congenital infection [429,430]. The recommendation of a second treponemal test beyond 15 months as a way of retrospectively diagnosing congenital syphilis is not merely for epidemiologic use—an established diagnosis can help in medical and developmental follow-up evaluation of the child [224,431].

All infants and children should be evaluated thoroughly for the extent of disease if there is serologic evidence of treatment failure or of recurrent disease. Such evaluation at a minimum should consist of CSF examination and complete blood count and platelet count. Other tests, such as long bone radiographs, liver function tests, hearing evaluation, and ophthalmologic evaluation, should be performed as clinically indicated. Infants with congenital neurosyphilis (or unavailable, abnormal, or uninterpretable CSF WBC count or protein concentration or positive CSF VDRL) should have repeat clinical and CSF evaluations every 6 months until CSF indices are normal. A reactive CSF VDRL test at any time represents an indication for retreatment with a full 10- to 14-day course. If CSF WBC counts do not steadily decline at each examination or remain abnormal at 2 years, retreatment also is indicated [78,121,390].

Although treatment can cure the infection, the prognosis in treated congenital syphilis depends on the degree of damage before the initiation of therapy. Generally, the earlier treatment is initiated, the more likely it is that a satisfactory response can be obtained [225]. If marked damage to the fetus has occurred, treatment in utero may not prevent abortion, stillbirth, or neonatal death, and even if treatment keeps the newborn infant alive, stigmata can remain. If treatment is provided prenatally or within the first 3 months of life, and such stigmata have not yet become apparent, they generally can be prevented [276]. Interstitial keratitis is an exception; this complication does not seem to be responsive to specific antibiotic therapy. Occasionally, dramatic relief has been afforded by the use of corticosteroids and mydriatics, although relapses have occurred with cessation of corticosteroid therapy. Osseous lesions seem to heal independently of specific therapy. Treatment of congenital syphilis in the late stage does not reverse the stigmata [432].

## PROBLEMS ASSOCIATED WITH PENICILLIN THERAPY

### Penicillin Hypersensitivity

Skin testing for penicillin hypersensitivity with the major and minor determinants can reliably identify people at high risk of reacting to penicillin; currently, only the major determinant (benzylpenicilloyl poly-L-lysine) and penicillin G skin tests are available commercially. Testing with the major determinant of penicillin G is estimated to miss 3% to 6% of penicillin-allergic patients, who are at risk of serious or fatal reactions. A cautious approach (i.e., hospitalization) to penicillin therapy is advised when a patient cannot be tested with all of the penicillin skin test reagents. An oral or intravenous desensitization protocol for patients with a positive skin test result is available (www.cdc.gov/nchstp/dstd/penicillinG.htm) and should be performed in a hospital setting [390,433]. Oral desensitization is regarded as safer and easier to perform. Desensitization usually can be completed in approximately 4 hours, after which the first therapeutic dose of penicillin can be given [78,433].

### Jarisch-Herxheimer Reaction

Jarisch-Herxheimer reaction, a common occurrence in the treatment of acquired early syphilis in adults [434], consists of chills, fever (≥38° C [≥100.4° F]), generalized malaise, hypotension, tachycardia, tachypnea, accentuation of cutaneous lesions, leukocytosis, and, exceedingly rarely, death. The reaction begins within 2 hours of treatment, peaks at approximately 8 hours, and disappears in 24 to 36 hours. The cause of Jarisch-Herxheimer reaction is unknown [435], although release of *T. pallidum* membrane lipoproteins that stimulate proinflammatory cytokines likely explains this clinical phenomenon [436]. Approximately 40% of pregnant women who receive treatment for syphilis exhibit a Jarisch-Herxheimer reaction [437,438]. In addition, these women may experience the onset of uterine contractions and preterm labor, with decreased fetal activity and fetal heart rate changes, including late decelerations, which last 24 to 48 hours and may lead to fetal death. No prophylactic measure or treatment is currently available. Abnormal ultrasound findings in the fetus and fetal monitoring for 24 hours may identify pregnancies at highest risk, but concern for occurrence of Jarisch-Herxheimer reaction should not delay treatment [438,439].

In congenital syphilis, the incidence of Jarisch-Herxheimer reaction is low, although it may be more common when treatment occurs later in infancy [242]; when it does occur, it varies in severity, ranging from fever to cardiovascular collapse and seizures [149]. In the series by Platou and Kometani [233], almost half of the infants sustained a febrile reaction during the first 36 hours after initiation of penicillin therapy. No relationship was observed between the severity or the outcome of the infection and this temperature elevation.

### Penicillin Shortage

During periods of penicillin shortage, see http://www.cdc.gov/nchstp/dstd/penicillinG.htm for updates. Currently, the following is recommended: [50]

1. For infants with clinical *definitive* or *highly probable* congenital syphilis, check local sources for aqueous crystalline penicillin G (potassium or sodium). If intravenous penicillin G is limited, substitute some or all daily doses with procaine penicillin G (50,000 U/kg/dose intramuscularly a day in a single daily dose for 10 days). If aqueous or procaine penicillin G is unavailable, ceftriaxone (in doses according to age and weight) may be considered with careful clinical and serologic follow-up. Ceftriaxone must be used with caution in infants with jaundice. For infants 30 days or more of age, use 75 mg/kg intravenously or intramuscularly a day in a single daily dose for 10 to 14 days; dose adjustment might be necessary based on birth weight. For older infants, the dose should be 100 mg/kg/d in a single dose. Studies that strongly support ceftriaxone for the treatment of congenital syphilis have not been conducted. Ceftriaxone should be used in consultation with a specialist in the treatment of infants with congenital syphilis. Management may include a repeat CSF examination at age 6 months if the initial examination was abnormal.
2. For infants at risk with probable or possible congenital syphilis, use procaine penicillin G, 50,000 U/kg/dose intramuscularly a day in a single dose for 10 days, or benzathine penicillin G, 50,000 U/kg intramuscularly as a single dose. If any part of the evaluation for congenital syphilis is abnormal, CSF examination is not interpretable, CSF examination was not performed, or follow-up is uncertain, procaine penicillin G is recommended. A single dose of ceftriaxone is not considered adequate therapy.
3. For premature infants with probable or possible congenital syphilis and who might not tolerate intramuscular injections because of decreased muscle mass, intravenous ceftriaxone may be considered with careful clinical and serologic follow-up. Ceftriaxone dosing must be adjusted to age and birth weight [50].

## PREVENTION

The history of syphilis prevention, reviewed by Hossain and colleagues [12], holds important lessons for prevention of congenital syphilis. Reports of attempts to understand and control syphilis in the 15th century can be found. Throughout Europe, legislation previously penalized infected individuals who knowingly infected others or did not complete treatment. The introduction of the Wassermann test in 1907 helped to increase the momentum of "venereal disease" control efforts, and public health efforts began to adapt to the changing epidemiologic nature and social perception of a stigmatized infection. By 1943, "rapid treatment centers" were available in the United States with 5 to 10 days of arsenical therapy; in Europe, venereal disease clinics opened providing free and confidential treatment with Ehrlich's salvarsan.

Europe and the United States saw a 90% decline in congenital syphilis from 1941–1972 with the widespread availability of screening and penicillin, the promotion of treatment of sexual partners, and blood donor screening. This success was attributed to policies providing free treatment, case finding and control, public education, a high degree of political will, and cooperation between medical professionals and the national health department. Initial public health efforts to combat this preventable infection in pregnancy arose in the 1940s in the form of antenatal syphilis screening and surveillance programs. Concepts developed by these early syphilis control strategies provided the model used by current sexually transmitted infection control programs, including HIV/AIDS: early identification, effective treatment of the index case and partner, intense follow-up, and behavioral modification of high-risk sexual practices.

Out of these historical lessons, concrete suggestions to halt the current increase in congenital syphilis have been extracted and have been summarized by Walker and Walker [111] and Schmid [16]. The cornerstone of immediate congenital syphilis control is antenatal screening and treatment of infected mothers with penicillin, which is a cost-effective intervention across the globe. In affluent countries, screening needs to be strengthened among people at high risk, who are most often society's marginalized groups [84,440], and clinicians need to be ever more vigilant for the possibility of infants born with congenital syphilis. In less developed countries, high priority needs to be given to improving the efficiency of antenatal screening and the treatment and management of infected neonates. This management includes promoting early attendance for antenatal care and educating women (and men) about the benefits of syphilis screening and treatment; promoting modification of high-risk sexual behavior and use of condoms; implementing decentralized same-day screening and treatment, and using more recently developed rapid heat-stable point-of-care screening tests; performing a second test late in pregnancy to manage reinfections; testing all women at delivery; and prompt treatment of all infants who have confirmed, probable, or suspected congenital syphilis. Where health infrastructures are weak and syphilis prevalence is high, total reliance on a complex system of antenatal screening and treatment is unrealistic, and alternative strategies, such as mass treatment, might offer a more cost-effective initial approach for controlling congenital syphilis. Because of lack of commitment of politicians and public health officials in charge, funds for the control—much less the elimination—of congenital syphilis are inadequate. This situation allows syphilis to increase once more [111].

## PRENATAL SCREENING

Although the concept of screening every pregnant woman for syphilis is simple, implementing the program may not be [16]. Screening of pregnant mothers for syphilis ranges from 17% to 88% in Bolivia, 63.6% to 79% in Brazil,

51% to 81% in Kenya, 43.2% in Malawi, less than 5% to 40% in Mozambique, 83.2% in Tanzania, and 32% to 83.2% in the United States. Despite these disparities in screening, in every society, the main cause of congenital syphilis is similar: lack of appropriate antenatal care [118]. In the industrialized world, failure to attend antenatal care is the most common cause of congenital syphilis with late care (too late to prevent stillbirth) a major contributing factor [353,441]. In the developing world, only an estimated 68% of pregnant women receive prenatal care, and the average time of first attendance is late—5 to 6 months [16]. For antenatal care to work, testing must be available and accessible. Availability can be addressed by decentralization of testing [442,443]. Accessibility argues that testing and treatment should be free of charge; cost to the patient has been identified as the greatest impediment to syphilis testing in sub-Saharan Africa [113]. Ideally, every woman who becomes pregnant should undergo at least one serologic test for syphilis during the first trimester [179,306,350,444]. For communities and populations in which the prevalence of syphilis is high or for women in high-risk groups, repeated testing at the beginning of the third trimester (at 28 weeks of gestation) [114] and at delivery is recommended [50].

It is a national policy in the United States that no infant should be discharged from the nursery before results of maternal serologic screening have been documented [50]. Laws pertaining to prenatal syphilis screening exist in 46 of the 50 U.S. states and the District of Columbia. Of these, 34 state laws mandate at least one prenatal serology, and 12 include a third-trimester test for either all or high-risk women [445]. The presence of state laws tends to correlate with the burden of congenital syphilis among the states [121]. With the practice of early discharge at 48 hours or less, it becomes the responsibility of the health care provider to arrange for adequate follow-up in infants who are discharged before the result of the maternal serologic test is known. The alternative to prenatal screening, targeted testing, is impractical to implement and would save little money, even if rates of syphilis were to decline in women and infants [287].

Prenatal testing systems do not help women who do not enter the medical care system until the moment before delivery. Lack of prenatal care, as already mentioned, is the most important cause for the persistence of congenital syphilis despite the wide availability of effective penicillin therapy [16,111]. Congenital syphilis is preventable, but only if prenatal care is available to and sought by the often hard-to-reach groups that are most at risk, such as teenage mothers, drug users, sex trade workers [446], and members of disadvantaged minority groups.

Several investigators have called attention to problems with antenatal management and communication crucial to the prevention of congenital syphilis [117,447–449]. These problems include failure to (1) obtain an appropriate and complete maternal history, (2) perform routine screening at appropriate times during the pregnancy, (3) interpret serologic results correctly, (4) recognize signs of maternal syphilis, (5) provide treatment for the pregnant sexual partner of an acutely infected man, and (6) communicate pertinent maternal history and results of screening tests to the infant's health care practitioner. Local health departments and clinicians must improve the exchange of information between obstetric and pediatric services. These issues underscore further the need for education of health care providers on the management of sexually transmitted diseases. Given the limitation of current screening serologic tests to detect early cases of syphilis, even a perfectly executed prenatal prevention strategy would not eliminate all congenital syphilis [300]. Other measures are needed in conjunction with optimal prenatal screening policies. Contact tracing of sexual partners, careful physical examination of women in labor for evidence of primary syphilis, and additional testing of postpartum women at 4 to 6 weeks after delivery represent steps that would potentially be helpful [60,92,242,362].

Beyond the obvious medical and ethical advantages, universal screening of every pregnant woman for syphilis would save more money than it costs. As reviewed by Walker and Walker [111] and Schmid [16], economic evaluations of antenatal syphilis screening programs have been conducted in developed and developing countries and shown significant cost-effectiveness in either setting [450]. In the developed world and some middle-income countries where the prevalence of syphilis is lower, studies have shown universal screening of pregnant women to be cost-effective because treatment and support for the cases of missed congenital syphilis in such settings are extremely expensive. In the United States, an infant with congenital syphilis is hospitalized, on average, for 7.5 days longer than other infants and costs, on average, an additional US$5253 (2001 prices). The inclusion of indirect costs sharply increases the cost per case of congenital syphilis. Compared with these costs, syphilis screening is inexpensive. Where syphilis prevalence is extremely low, targeted screening might be marginally more cost-effective, but the political cost and practical difficulties of implementing this are considered to be unacceptably high.

In low-income countries, where the prevalence of syphilis remains high, fewer economic evaluations have been performed. In contrast to developed countries, the direct costs of congenital syphilis are relatively modest. Nevertheless, studies have found that screening is an efficient use of scarce resources. Terris-Prestholt and associates [451] estimated the cost per disability adjusted life year (DALY) averted in Tanzania and compared this with other studies from Zambia and Kenya in terms of the cost per DALY averted, which included all fetal consequences of maternal syphilis (i.e., abortions, stillbirths, low birth weight, and congenital syphilis). The cost per DALY averted was estimated to be US$3.97 to US$18.73 (2001 prices). Based on the recommendation of the Commission on Macroeconomics and Health, the WHO classifies interventions as "highly cost-effective" for a given country if results show that they avert a DALY for less than the per capita national gross domestic product, so antenatal syphilis screening is highly cost-effective in most developing countries. These calculations do not take into account the additional benefit of detecting and treating infection in the woman and her partner or partners [118]. As health

care systems increasingly concentrate on preventing HIV infection in infants born to mothers with HIV infection, it is inexplicable that they do not do the same for syphilis because prevention of one DALY owing to congenital syphilis in a screening program for maternal syphilis using traditional testing methods is about 25 times more cost-effective as preventing one DALY among infants born to women who are HIV-positive [451,452].

## CONTACT INVESTIGATION

Mothers of infants with congenital syphilis should be evaluated for gonorrhea, *C. trachomatis*, HIV, hepatitis B, and potentially hepatitis C infections. All cases should be reported to local public health authorities, who should undertake evaluation of recent sexual contacts for possible sexually transmitted diseases [50,85]. Patients who have had sexual contact with an untreated person should have a full clinical evaluation, serologic testing, and treatment. The time periods before treatment used for identifying at-risk sexual partners are (1) 3 months plus duration of symptoms for primary syphilis, (2) 6 months plus duration of symptoms for secondary syphilis, and (3) 1 year for early latent syphilis [50]. Persons who were exposed within 90 days preceding the diagnosis of primary, secondary, or early latent syphilis in a sexual partner might be infected even if seronegative and should receive presumptive treatment.

As partner notification has become more challenging because of anonymous sex and the inability to locate sexual partners, attention has focused on identifying core environments and populations in which syphilis transmission is occurring at a high rate [453]. Such knowledge has resulted in provision of prophylactic syphilis treatment to groups of people in high-risk populations (see subsequent section). The CDC has designed a strategy to assist public health providers at state and local levels to design interventions for targeted at-risk populations. Called the rapid ethnographic community assessment process (RECAP), the assessment is a package of activities and tools designed to use ethnographic methods for improving community involvement and developing interventions that fit a population's social and behavioral context [85].

## MASS TREATMENT PROGRAMS

When enhancements of standard public health measures, such as contact tracing, education of at-risk groups and physicians, increased diagnostic and treatment services, and intensified screening, cannot control outbreaks, an alternative employed in developing and developed countries with some success is targeted mass treatment. The British Columbia Centre for Disease Control implemented a mass treatment and prophylaxis program with good short-term success, delivering more than 7000 treatment doses of azithromycin (1.8 g orally in a single dose) in two rounds over 5 weeks for syphilis to adults at high risk [93–95]. A later rebound in numbers of cases occurred, however, which is presumed to have been due to incomplete coverage of "high-frequency transmitters." [94,454] A similar program in Rinakai, Uganda, delivered more than 20,000 1-g treatment doses of azithromycin [455–457]. The use of azithromycin and oral forms of penicillin offers advantages over the traditional use of injectable penicillin in terms of compliance [287,458]. More recent reports of azithromycin-resistant *T. pallidum* in the United States, where the use of azithromycin is far higher than in sub-Saharan Africa, indicate the potential problems associated with its use for syphilis [459,460]. Two smaller scale mass treatment programs in North America had been conducted using benzathine penicillin G, and both were judged successful [461,462]. There currently is no evidence to suggest that oral treatment is sufficient for the treatment of syphilis in pregnancy [458,463].

## EDUCATION

Despite great progress in recent years, the prevention, control, and elimination of endemic syphilis in North America and other developed countries remains an elusive goal in public health policy. This is also true on a global scale in countries where resources may be limited and, as explained earlier, the practicalities of serologic screening and treatment in prenatal care settings are challenging. Another way to counteract the spread of syphilis and other sexually transmitted infections is through sexual education. The surest way to avoid transmission of sexually transmitted diseases, including syphilis, is to abstain from sexual contact or to be in a long-term, mutually monogamous relationship with a partner who has been tested and is known to be uninfected [50,85].

As outlined by the CDC, syphilis occurs in male and female genital areas that are covered or protected by a latex condom. The chancres also occur in areas that are not covered, and a substantial proportion (13.7%) of syphilis cases are attributed to oral sex [50,85]. Correct and consistent use of latex condoms can reduce the risk of syphilis, but does not eliminate the risk of transmission. Condoms lubricated with spermicides (especially nonoxynol 9) are no more effective than other lubricated condoms and are not recommended for sexually transmitted disease and HIV prevention. Persons who are not in a long-term monogamous relationship and who engage in oral sex should use appropriate barrier protection to reduce the risk for transmission of syphilis or other sexually transmitted infections. Just as important as it is that sex partners talk to each other about their HIV status and history of other sexually transmitted infections so that preventive action can be taken, it is equally important for the physician to educate sexually active patients continually [50,85].

## ADVOCACY

The World Health Assembly stated in May 2006 in its "Strategy for the Prevention and Control of Sexually Transmitted Infections" that elimination of congenital syphilis is a global priority and emphasized the importance of incorporating this fight against congenital syphilis into wider initiatives that deal with the spread of sexually transmitted infections and HIV in general [111]. The Department of Reproductive Health and Research (RHR) at WHO published a series of "state-of-the-art"

reviews on maternal and congenital syphilis in the *Bulletin of the World Health Organization* to advocate for action for the elimination of congenital syphilis worldwide [16]. The Scientific Technical Advisory Group of RHR in WHO endorsed a strategy for the global elimination of congenital syphilis, and elimination of congenital syphilis was included in its 2004–2009 work plan [16,111].

The broad goal of the WHO Strategy is the elimination of congenital syphilis as a public health problem, with the specific goals of prevention of mother-to-child transmission of syphilis through early antenatal care for all women, treatment of all sexual partners of infected women, and prophylactic treatment with a single dose of penicillin of all neonates born to RPR-positive mothers. These goals, together with the reduction of prevalence of syphilis in pregnant women as stated in the WHO Strategy, would ensure sustainability of the elimination goal of congenital syphilis. The WHO Strategy at country level consists of four pillars: to ensure sustained political commitment and advocacy; to increase access to, and quality of, maternal and newborn health services; to screen and treat all pregnant women; and to establish surveillance, monitoring, and evaluation systems. In its report, the WHO promised to assume the necessary leadership role, ensuring that the elimination of congenital syphilis becomes an institutional priority.

No date has been set as a target for eliminating congenital syphilis. Rather, interim goals have been set to introduce operationally programs into countries to eliminate congenital syphilis. The WHO points out that countries do not face insurmountable obstacles in attempts to achieve elimination of congenital syphilis, but lack political commitment, evidence-based priority setting, and advocacy at all levels [16,111]. There is little reason why the elimination of congenital syphilis is not a priority for every nation, and many reasons why it should be.

## ACKNOWLEDGMENT

Drs. Ingall, Sanchez and Baker were co-authors of this chapter in previous editions.

CHAPTER 17

# *BORRELIA* INFECTIONS: LYME DISEASE AND RELAPSING FEVER

**Eugene D. Shapiro ❂ Michael A. Gerber**

CHAPTER OUTLINE

## LYME DISEASE

Lyme disease, caused by the spirochete *Borrelia burgdorferi*, is the most common vector-borne illness in the United States. Although, in retrospect, a form of the illness had been recognized in Scandinavia in the early 1900s, modern awareness of Lyme disease began after a cluster of cases of "juvenile rheumatoid arthritis" in children living on one small street was reported by their parents in the mid-1970s. Investigation of this unexplained "epidemic" of arthritis led to the description of "Lyme arthritis" in 1976 and, ultimately, to the discovery of its bacterial etiology [1–3]. The reported incidence of Lyme disease and its geographic range have increased dramatically in recent years [4].

Several spirochetes are known to cause transplacental infections in various animals and in humans [5–17]. *Treponema pallidum* has been the most thoroughly investigated spirochete with respect to transplacental transmission in humans [5]. Infection of the mother with *T. pallidum* during pregnancy frequently is associated with transplacental infection, resulting in congenital syphilis in the offspring. Congenital syphilis often is associated with clinically significant neurologic disease, such as hydrocephalus, cerebral palsy, deafness, blindness, convulsive disorders, and mental retardation [5]. Adverse fetal outcomes also have been documented in gestational infections with *Leptospira canicola*, the etiologic agent of leptospirosis, and with other *Borrelia* species, including the etiologic agents of relapsing fever (discussed later) [7–17]. Because *B. burgdorferi* is a spirochete, whether it too can cause congenital infection naturally is of considerable interest.

### EPIDEMIOLOGY AND TRANSMISSION

*B. burgdorferi* is transmitted by species of ticks of the *Ixodes* genus. In the United States, the usual vector in the Northeast and the upper Midwest is *Ixodes scapularis* (the black-legged tick), commonly called the deer tick, whereas *Ixodes pacificus* (the Western black-legged tick) is the usual vector on the Pacific Coast [18]. In Europe, the most important vector for the spirochete is *Ixodes ricinus*, which commonly feeds on sheep and cattle.

The life cycle of *I. scapularis* consists of three stages—larva, nymph, and adult—that develop during a 2-year period [18]. Ticks feed once during each stage of the life cycle. The larvae emerge in the early summer from eggs laid in the spring by the adult female tick. More than 95% of the larvae are born uninfected with *B. burgdorferi* because transovarial transmission rarely occurs. The larvae feed on a wide variety of small mammals, such as the white-footed mouse, which are natural reservoirs for *B. burgdorferi*. Larvae become infected by feeding on animals that are infected with the spirochete. The tick emerges the following spring in the nymphal stage. This stage of the tick is most likely to transmit infections to humans [19], presumably because it is active at times during which humans are most likely to be in tick-infested areas and because it is very small and difficult to see. Consequently, it is more likely to be able to feed for a relatively long time, which increases the likelihood of transmission. If the nymphal tick is not infected with *B. burgdorferi*, it may subsequently become infected if it feeds on an infected animal in this stage of its development. The nymphs molt in the late summer or early fall and reemerge as adults. If the adult is infected, it also may transmit *B. burgdorferi* to humans. The adult deer tick may spend the winter on an animal host, a favorite being white-tailed deer (hence its name, the deer tick). In the spring, the females lay their eggs and die, completing the 2-year life cycle.

Numerous factors are associated with the risk of transmission of *B. burgdorferi* from infected ticks to humans. The proportion of infected ticks varies greatly by geographic area and by the stage of the tick in its life cycle. *I. pacificus* often feeds on lizards, which are not a competent reservoir for *B. burgdorferi*. Consequently, less than 5% of these ticks are infected with *B. burgdorferi*, so Lyme disease is rare in the Pacific states. By contrast, *I. scapularis* feeds on small mammals, which are competent reservoirs for *B. burgdorferi*. As a result, in highly endemic areas the rates of infection for different stages of deer ticks are, approximately, 2% for larvae, 15% to 30% for nymphs, and 30% to 50% for adults.

DOI: 10.1016/B978-1-4160-6400-8.00017-1

*B. burgdorferi* is transmitted when an infected tick inoculates saliva into the blood vessels of the skin of its host. The risk of transmission of *B. burgdorferi* from infected deer ticks has been shown to be related to the duration of feeding. It takes hours for the mouth parts of ticks to implant in the host, and much longer (days) for the tick to become fully engorged from feeding. *B. burgdorferi* is found primarily in the midgut of the tick, but as the tick feeds and becomes engorged, the bacteria migrate to the salivary glands, from which they can be transmitted. Experiments with animals have shown that infected nymph-stage ticks must feed for 48 hours or longer and infected adult ticks must feed for 72 hours or longer before the risk of transmission of *B. burgdorferi* becomes substantial [20–22]. Results of a study of transmission of Lyme disease to humans are consistent with these experimental results [19]. Among persons bitten by nymph-stage ticks for which the duration of feeding could be estimated, the risk of Lyme disease was zero among persons bitten by nymphs that had fed for less than 72 hours, but was 25% among persons bitten by nymphs that had fed for 72 hours or more. Approximately 75% of persons who recognize that they have been bitten by a deer tick remove the tick within 48 hours after it has begun to feed [23], which may explain why only a small proportion of persons who recognize that they have been bitten by deer ticks subsequently develop Lyme disease. The risk of Lyme disease probably is greater from unrecognized bites because in such instances the tick is able to feed for a longer time.

Substantial evidence indicates that the risk of Lyme disease after a recognized deer tick bite, even in hyperendemic areas, is only 1% to 3% [19,24,25]. The expertise to identify the species, stage, and degree of engorgement of a tick—and to assess the degree of risk—is rarely available to individuals who are bitten. Many "ticks" submitted for identification by physicians turned out actually to be spiders, lice, scabs, or dirt, none of which can transmit Lyme disease. In addition, estimates by patients of the duration for which the tick fed are unreliable [26].

Lyme disease occurs throughout the world (Fig. 17–1). In the United States, most cases occur in a few highly endemic areas—southern New England, New York, New Jersey, Pennsylvania, Minnesota, and Wisconsin (Fig. 17–2) [4]. In Europe, most cases occur in the Scandinavian countries and in central Europe (especially in Germany, Austria, and Switzerland), although cases have been reported from throughout the region.

Although an increase in frequency and an expansion of the geographic distribution of Lyme disease in the United States have occurred in recent years, the incidence of Lyme disease even in endemic areas varies substantially—from region to region and within local areas. Information about the incidence of the disease is complicated by reliance, in most instances, on passive reporting of cases and by the high frequency of misdiagnosis of the disease.

**FIGURE 17–1** Worldwide geographic distribution of reported Lyme disease.

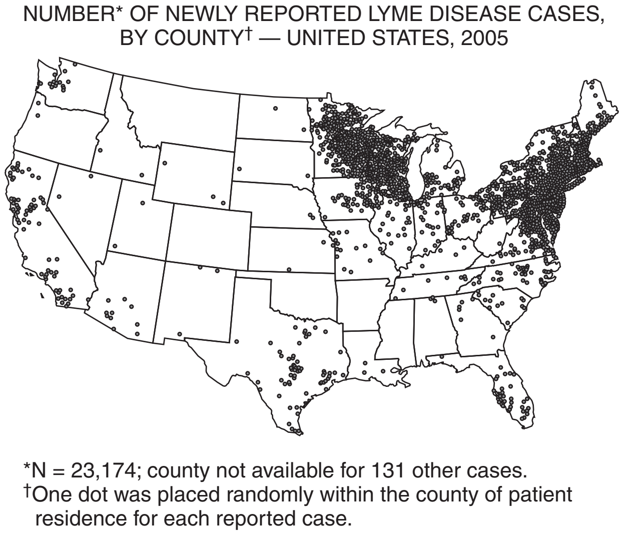

**FIGURE 17–2** Number of cases of Lyme disease, by county in the United States, 2005. *(From CDC. Lyme disease—United States, 2003-2005. MMWR Morb Mortal Wkly Rep 56:573-576, 2007. Available at http://www.cdc.gov/mmwr/preview/mmwrhtml/mm5623a1.htm.)*

Studies have indicated that some patients in whom serologic evidence of recent infection with *B. burgdorferi* develops are asymptomatic [27,28].

From 2003-2005, 64,382 cases of Lyme disease were reported to the U.S. Centers for Disease Control and Prevention (CDC) (an average of 21,460 cases/yr) [4]. Of the cases, 93% (29.2 cases per 100,000 population) were reported in just 10 states (Connecticut, Delaware, Maryland, Massachusetts, Minnesota, New Jersey, New York, Pennsylvania, Rhode Island, and Wisconsin) (see Fig. 17–2).

## MICROBIOLOGY

The spirochetal bacterium *B. burgdorferi* is a fastidious, microaerophilic organism that in vitro must be grown on special media. It is a slow-growing bacterium with a cell membrane that is covered by flagella and a loosely associated outer membrane. Major antigens of the bacteria include the outer surface lipoproteins OspA, OspB, and OspC (highly charged basic proteins of molecular masses of about 31 kDa, 34 kDa, and 23 kDa) and the 41-kDa flagellar protein. The organism is more properly classified as the *Borrelia burgdorferi sensu lato* ("in the broad sense") species complex, which has been subclassified into several genomospecies, among which the major ones that cause human diseases are *Borrelia burgdorferi sensu stricto* ("in the strict sense"), *Borrelia garinii*, and *Borrelia afzelii*. In the United States, only *B. burgdorferi sensu stricto* has been isolated from humans. By contrast, substantial variability exists in the species of *B. burgdorferi* isolated from humans in Europe, most of which are either *B. garinii* or *B. afzelii*. The complete genome of the organism has been sequenced [29]. The biology of *B. burgdorferi* is complex, as might be expected in view of the complicated life cycle of this vector-borne bacterium, part of which is spent in ticks (with a primitive immune system) and part of which is spent in mammals, which have a highly evolved immune system. The reader is referred to other sources for detailed discussion of the biology of this organism [30].

## PATHOGENESIS AND PATHOLOGY

In approximately 90% of patients in the United States, Lyme disease begins with the characteristic expanding skin lesion, erythema migrans, at the site of the tick bite [31,32]. The spirochete subsequently disseminates via the bloodstream, producing the malaise, fatigue, headache, arthralgia, myalgia, fever, and regional lymphadenopathy that may be associated with early Lyme disease and the clinical manifestations of early disseminated and, ultimately, of late Lyme disease. The ability of the spirochete to spread through skin and other tissues may be facilitated by the binding of human plasminogen and its activators to the surface of the organism [33]. During dissemination, *B. burgdorferi* attaches to certain host integrins [34,35], matrix glycosaminoglycans [36], and extracellular matrix proteins [37], which may explain the organism's particular tissue tropisms (e.g., collagen fibrils in the extracellular matrix in the heart, nervous system, and joints) [36]. In addition, the sequences of OspC vary considerably among strains, and only a few groups of sequences are associated with disseminated disease [38].

Studies in mice have shown the importance of inflammatory innate immune responses in controlling early disseminated Lyme disease [39,40]. In humans with erythema migrans, infiltrates of macrophages and T cells produce inflammatory and anti-inflammatory cytokines [41]. In addition, evidence suggests that in disseminated infections, adaptive T-cell and B-cell responses in lymph nodes produce antibodies against many components of the spirochete [42,43].

The mechanism by which *B. burgdorferi* interacts with the host immune responses to produce Lyme neuroborreliosis or Lyme arthritis is not fully understood [44–47]. In the initial attempt to eliminate *B. burgdorferi*, the innate immune response to the organism results in the release of cytokines, chemokines, and other immune mediators that produce an inflammatory response. This inflammatory response damages host tissues in the process of attempting to eradicate the *Borrelia* organisms. Subsequently, an adaptive immune response is initiated through the processing and presentation of *B. burgdorferi* antigens by macrophages and dendritic cells. This response results in the release of additional immune mediators, which exacerbate further the damage produced by the inflammatory response [44–47].

Several spirochetes have exhibited the ability to cause transplacental infections in various animals and in humans [5–17]. Transplacental transmission of *B. burgdorferi* has been documented in several animal studies, including case reports, case series, and transmission studies. *B. burgdorferi* has been cultured from fetal tissues of a coyote and a white-footed mouse and from the blood of a newborn calf [48–50]. The presence of *B. burgdorferi* in fetal tissues of a white-footed mouse and a house mouse also has been shown by polymerase chain reaction (PCR) assay [51]. Serologic evaluations also have been used to document in utero fetal infection with *B. burgdorferi* in an aborted calf, a newborn foal, and four beagle pups [49,50,52].

Several animal studies have linked infection with *B. burgdorferi* during pregnancy with fetal wastage and reproductive failure in cows and beagles [50,52]. Infection with *B. burgdorferi* during pregnancy also has been associated with reproductive failure and severe fetal infection in horses [53] and with increased fetal loss in mice [54].

In animal experiments, transplacental transmission of *B. burgdorferi* was documented by PCR assay in 19 of 40 pups born to female beagles that had been intradermally inoculated with this spirochete multiple times during pregnancy [52]. Only 4 of the 19 pups had culture-positive tissues, and none of the pups had any evidence of inflammation. In other studies, female rats inoculated with *B. burgdorferi* intraperitoneally at 4 days of gestation and pregnant hamsters infected by tick bite just before gestation showed no evidence by culture of transplacental transmission of *B. burgdorferi* to their offspring [55,56]. In another study, offspring of naturally infected white-footed mice were unable to transmit *B. burgdorferi* to spirochete-free deer ticks allowed to feed on them [57].

Transplacental transmission of *B. burgdorferi* in humans has been shown in association with adverse fetal outcome in several case reports. The first was a report by Schlesinger and coworkers in 1985 [58] that described a 28-year-old woman with untreated Lyme disease during the first trimester of pregnancy, who gave birth, at 35 weeks of gestation, to an infant with widespread cardiovascular abnormalities. The infant died during the first week of life, and postmortem examination showed spirochetes morphologically compatible with *B. burgdorferi* in the infant's spleen, kidneys, and bone marrow, but not in the heart. In contrast with the mononuclear cell infiltrate and proliferation of fibroblasts usually seen with congenital syphilis [59], there was no evidence of inflammation, necrosis, or granuloma formation in the infant's heart or other organs. In 1987, MacDonald and coworkers [60] described a 24-year-old woman with untreated Lyme disease in the first trimester of pregnancy who gave birth at term to a stillborn infant weighing 2500 g. *B. burgdorferi* was cultured from the liver, and spirochetes were seen in the heart, adrenal glands, liver, brain, and placenta with immunofluorescence and silver staining techniques. No evidence of inflammation was seen, however, and no abnormalities were noted except for a small ventricular septal defect.

Weber and colleagues in 1988 [61] described a 37-year-old woman who received penicillin orally for 1 week for erythema migrans during the first trimester of pregnancy. She subsequently gave birth to a 3400-g infant at term who died at 23 hours of age, of what was believed to be "perinatal brain damage." *B. burgdorferi* was identified in the newborn's brain using immunochromogenic staining with monoclonal antibodies. No significant inflammation or other abnormalities were found, however, in any organ, including the brain, on postmortem examination. In 1997, Trevisan and associates [62] described an otherwise healthy infant who presented with multiple annular erythematous lesions, fever, and generalized lymphadenopathy at 3 weeks of age. These clinical abnormalities recurred throughout the first 3 years of life despite oral therapy with amoxicillin and josamycin. A skin biopsy specimen revealed spirochetes by silver stain and was positive for *B. burgdorferi* by PCR assay. In addition, serologic studies were positive for infection with *B. burgdorferi*. The patient's mother had no history of either a tick bite or Lyme disease, but she had been involved in outdoor activities in an endemic area and had a weakly positive serologic test for Lyme disease.

Several case reports have described pregnant women with either erythema migrans or neuroborreliosis who received appropriate antimicrobial therapy at different stages of their pregnancies [63–67]. In none of these reports was there an association between Lyme disease in the mother and an adverse outcome of the pregnancy.

Transplacental transmission of *B. burgdorferi* also has been investigated in a study of 60 placentas from asymptomatic women who lived in an area endemic for Lyme disease and whose results on serologic testing by enzyme-linked immunosorbent assay (ELISA) were either positive or equivocal for antibodies to *B. burgdorferi* [68]. All 60 placentas were examined with a Warthin-Starry silver stain for evidence of infection with *B. burgdorferi*; 3 (5%) were positive for spirochetes. PCR assays for *B. burgdorferi* nucleotide sequences were performed on two of these three placentas and were positive in both. The women from whom these three placentas were obtained all had equivocal results on ELISAs and negative results on Western blot analysis for Lyme disease and negative results on serologic tests for syphilis. In addition, none of these women had a history of either a tick bite or a clinical course consistent with Lyme disease. All of these pregnancies had entirely normal outcomes.

In addition to the individual case reports, several published case series have assessed the relationship between Lyme disease in pregnant women and fetal outcomes. Two of these case studies were conducted by the CDC. The first was a retrospective investigation conducted in 19 women with Lyme disease during pregnancy who were identified by the investigators without knowing the fetal outcomes [69]. The adverse outcomes included prematurity, cortical blindness, intrauterine fetal death, syndactyly, and a generalized neonatal rash. Infection with *B. burgdorferi* could not be directly implicated as the cause of any of these outcomes, however. The second case series included 17 women who acquired Lyme disease during pregnancy and were evaluated prospectively [70]. One woman had a spontaneous abortion with no evidence of an infection with *B. burgdorferi* on either stains or cultures of the fetal tissue, 1 woman had an infant with isolated syndactyly, and 15 women were delivered of normal infants with no clinical or serologic evidence of infection with *B. burgdorferi*.

In 1999, Maraspin and coworkers [71] reported a series of 105 women with erythema migrans during pregnancy. Ninety-three (88.6%) of the 105 women had healthy infants delivered at term, 2 (1.9%) pregnancies ended with a miscarriage, and 6 (5.7%) ended with a preterm birth. One of the preterm infants had cardiac abnormalities, and two died shortly after birth. Four (3.8%) infants born at term had congenital anomalies (one with syndactyly and three with urologic abnormalities). As with a previous study, infection with *B. burgdorferi* could not be directly implicated as the cause of any of these adverse outcomes.

Several epidemiologic studies of Lyme disease during pregnancy also have been conducted. In the first, Williams and coworkers [72] examined 421 serum specimens obtained from cord blood and found no association between the presence of IgG antibodies to *B. burgdorferi* and congenital malformations. In another study, Nadal and associates [73] investigated outcomes in 1434 infants of 1416 women for the presence of antibodies to *B. burgdorferi* at the time of delivery. Of the women, 12 (0.85%) were found to be seropositive, but only 1 woman had a history consistent with Lyme disease during pregnancy. Of the infants born to the 12 seropositive women, 2 had transient hyperbilirubinemia; 1 had transient hypotonia; 1 was post-term and small for gestational age, with evidence of chronic placental insufficiency; 1 had transient macrocephaly; and 1 had transient supraventricular extra beats. The infant born to the woman with a clinical history of Lyme disease during pregnancy had a ventricular septal defect. At follow-up evaluations approximately 9 to 17 months later, all of the children except for the child with the cardiac defect were entirely well, and none had serologic evidence of infection with *B. burgdorferi*.

In 1994, Gerber and Zalneraitis [74] surveyed neurologists in areas of the United States in which Lyme disease was endemic at that time to determine how many had seen a child with clinically significant neurologic disease whose mother had been diagnosed as having Lyme disease during pregnancy. None of the 162 pediatric and 37 adult neurologists who responded to the survey had ever seen a child whose mother had been diagnosed with Lyme disease during pregnancy. The investigators concluded that congenital neuroborreliosis was either not occurring or occurring at an extremely low frequency in areas endemic for Lyme disease. In a retrospective case-control study carried out in an area endemic for Lyme disease, 796 "case" children with congenital cardiac anomalies were compared with 704 "control" children without cardiac defects with respect to Lyme disease in their mothers either during or before the pregnancy [75]. No association was found between congenital heart defects and either a tick bite or Lyme disease in the mothers either within 3 months of conception or during pregnancy.

Investigators in New York performed two studies of the relationship between Lyme disease in pregnant women and adverse outcomes of the pregnancies. The first was an unselected, prospective, population-based investigation in an area endemic for Lyme disease in which approximately 2000 women in Westchester County, New York, were evaluated for clinical and serologic evidence of Lyme disease at the first prenatal visit and again at delivery [76]. Of these women, 11 (0.7%) were seropositive, and 79 (4%) reported at the first prenatal visit that they had had Lyme disease sometime in the past. One woman with an untreated influenza-like illness in the second trimester had a negative result on serologic testing for Lyme disease at the prenatal visit, but a positive result at delivery. In addition, during the study period, clinical Lyme disease was diagnosed in 15 pregnant women. No association was found between exposure of the mother to *B. burgdorferi* either before conception or during pregnancy and fetal death, prematurity, or congenital malformations. In the second study, the researchers compared 5000 infants, half from an area in which Lyme disease was endemic and half from an area without Lyme disease, who served as controls. The researchers found no significant difference in the overall incidence of congenital malformations between the two groups [77]. Although there was a statistically significant higher rate of cardiac malformations in the endemic area compared with that in the control area, no relationship was noted between a cardiac malformation and either a clinical history or serologic evidence of Lyme disease. The researchers concluded from the findings of these two studies that a pregnant woman with a past infection with *B. burgdorferi*, either treated or untreated, did not have an increased risk of early fetal loss or of having a low birth weight infant or an infant with congenital malformations [77].

Two reports have documented the presence of *B. burgdorferi* in cow's milk. In 1988, Burgess [50] cultured *B. burgdorferi* from 1 of 3 samples of colostrum from cows, but from none of 44 samples of cow's milk. Lischer and colleagues [78] used a PCR assay to identify nucleotide sequences of *B. burgdorferi* in the milk of a cow with clinical Lyme disease. In a similar investigation of human milk, Schmidt and coworkers [79] examined breast milk from two lactating women with erythema migrans and from three lactating women with no clinical evidence of Lyme disease. The breast milk samples from both women with erythema migrans tested positive for *B. burgdorferi* by PCR assay, whereas the breast milk samples from all three healthy women tested negative. No other reports have corroborated these findings in human milk, however, and transmission of Lyme disease through breast-feeding has never been documented.

## CLINICAL MANIFESTATIONS

The clinical manifestations of Lyme disease depend on the stage of the illness—early localized disease, early disseminated disease, or late disease [31,80]. Erythema migrans, the manifestation of early localized Lyme disease, appears at the site of the tick bite, 3 to 30 days (typically 7 to 10 days) after the bite. Erythema migrans is found in about 90% of patients with objective evidence of infection with *B. burgdorferi* [31,32,81]. Erythema migrans begins as a red macule or papule and expands for days to weeks to form a large, annular erythematous lesion that ranges from 5 to 70 cm in diameter (median 15 cm). This rash may be uniformly erythematous, or it may appear as a target lesion with a variable degree of central clearing. It can vary greatly in shape and, occasionally, may have vesicular or necrotic areas in the center. Erythema migrans is usually asymptomatic, but may be pruritic or painful, and it may be accompanied by systemic findings, such as fever, malaise, headache, regional lymphadenopathy, stiff neck, myalgia, or arthralgia.

The most common manifestation of early disseminated Lyme disease in the United States is multiple erythema migrans. The secondary skin lesions, which usually appear 3 to 5 weeks after the tick bite, consist of multiple annular erythematous lesions similar to, but usually smaller than, the primary lesion. Other common manifestations of early disseminated Lyme disease are cranial

nerve palsies, especially facial nerve palsy, and meningitis. Systemic symptoms such as fever, myalgia, arthralgia, headache, and fatigue also are common in this stage of Lyme disease. Carditis, which usually is manifested by various degrees of heart block, is a rare manifestation of early disseminated disease [32].

The most common manifestation of late Lyme disease, which occurs weeks to months after the initial infection, is arthritis. The arthritis is usually monarticular or oligoarticular and affects the large joints, particularly the knee. Although the affected joint often is swollen and tender, the intense pain associated with a septic arthritis usually is not present; frequently, the swollen joint is only mildly symptomatic. Encephalitis, encephalopathy, and polyneuropathy also are manifestations of late Lyme disease, but they are rare.

The clinical manifestations of Lyme disease also may depend on which subspecies of *B. burgdorferi* is causing the infection [31]. The differences in subspecies found in Europe and in North America may account for differences in the frequencies of certain clinical manifestations of Lyme disease in these areas. Neurologic manifestations of Lyme disease are more common in Europe, whereas rheumatologic manifestations are more common in North America. In addition, certain skin and soft tissue manifestations of Lyme disease, such as acrodermatitis chronica atrophicans and lymphocytomas, occur in Europe, but are extremely rare in the United States.

There has been substantial controversy about an entity that has been called “chronic Lyme disease.” There is no evidence that such a condition exists [82]. Nonspecific symptoms (e.g., fatigue, arthralgia, or myalgia) may persist for several weeks, even in patients who are successfully treated for early Lyme disease; their presence should not be regarded as an indication for additional treatment with antimicrobials. These symptoms usually respond to nonsteroidal anti-inflammatory drugs. Within 6 months of completion of the initial course of antimicrobial therapy, these nonspecific symptoms usually resolve without additional antimicrobial therapy. For the unusual patients who have symptoms that persist longer than 6 months after the completion of antimicrobial therapy, an attempt should be made to determine whether these symptoms are the result of a postinfectious phenomenon or have another etiology [82].

Most patients with “chronic Lyme disease” have no evidence of either current or past infection with *B. burgdorferi*. There have been four double-blind randomized clinical trials of long-term antibiotic treatment for patients with at least some evidence of past infection with *B. burgdorferi* and subsequent symptoms that persist for at least 6 months after conventional (or longer) treatment with antibiotics [83–85]. The results of all of these studies showed that long-term treatment provided little or no benefit, but was associated with substantial risks to the patient [86]. In addition, prolonged use of antibiotics encourages selection of antibiotic-resistant bacteria that pose risks to the patients and to the community. These results add to the already substantial data that “chronic Lyme disease” is not a persistent infection, but more likely should be classified as a syndrome of medically unexplained symptoms [87].

*Ixodes* ticks may transmit other pathogens in addition to *B. burgdorferi*, including *Babesia*, *Anaplasma*, other *Borrelia* species, and viruses. These agents may be transmitted either separately from or simultaneously with *B. burgdorferi*. The frequency with which coinfection occurs is unknown. The impact of coinfection on the clinical presentation and the response to treatment of Lyme disease, although well documented and important in rare selected cases, seems to be of minor significance in most instances. In the south-central United States, in areas such as Missouri, another tick-borne infection that causes erythema migrans has been recognized: [88,89] Southern tick-associated rash illness (STARI) is transmitted by the tick *Amblyomma americanum*, the Lone Star tick. The organism that causes STARI, originally thought to be *Borrelia lonestari*, has not been identified, however. In contrast to Lyme disease, it does not seem to cause systemic disease. Similar to Lyme disease, there is no evidence that STARI is associated with congenital disease in children.

## DIAGNOSIS

The CDC clinical case definition for Lyme disease initially was intended for epidemiologic surveillance purposes [90]. When used in conjunction with CDC and U.S. Food and Drug Administration (FDA) guidelines for diagnostic tests [90–92], however, this case definition has been widely accepted as a means to standardize the clinical diagnosis of Lyme disease (Table 17–1).

**TABLE 17–1** CDC Lyme Disease Case Definition for Public Health Surveillance Purposes

| |
|---|
| Erythema migrans: Single primary red macule or papule, expanding over days to weeks to large round lesion ≥5 cm diameter (physician-confirmed), ± central clearing, ± secondary lesions, ± systemic symptoms (fever, fatigue, headache, mild neck stiffness, arthralgia, myalgia) |
| *Plus* |
| Known exposure ≤30 days before onset to endemic area (in which ≥2 confirmed cases have been acquired, or in which *Borrelia burgdorferi*–infected tick vectors are established) |
| *Or* |
| One or more late manifestations without other etiology |
| 1. Musculoskeletal: Recurrent brief episodes of monarticular or pauciarticular arthritis with objective joint swelling, ± chronic arthritis |
| 2. Neurologic: Lymphocytic meningitis, facial palsy, other cranial neuritis, radiculoneuropathy, encephalomyelitis (confirmed by CSF *B. burgdorferi* antibody > serum *B. burgdorferi* antibody) |
| 3. Cardiovascular: Acute second-degree or third-degree atrioventricular conduction defects, lasting days to weeks, ± myocarditis |
| *Plus* |
| Laboratory confirmation by either |
| 1. Isolation of *B. burgdorferi* from patient specimen |
| 2. Diagnostic levels of *B. burgdorferi* IgM or IgG antibodies in serum or CSF (initial ELISA or IFA screen followed by Western blot of positive or equivocal results) |

*CDC, Centers for Disease Control and Prevention; CSF, cerebrospinal fluid; ELISA, enzyme-linked immunosorbent assay; IFA, immunofluorescence assay.*
*Adapted from CDC. Case definitions for infectious conditions under public health surveillance. MMWR 1997;46(No. RR-10) 20-21, 1997.*

For patients in locations endemic for Lyme disease who present with the characteristic lesion of erythema migrans, the diagnosis of Lyme disease should be based on the clinical presentation alone. In such situations, laboratory testing is neither necessary nor recommended. With the exception of erythema migrans, however, the clinical manifestations of Lyme disease are nonspecific. For patients who do not have erythema migrans, the diagnosis of Lyme disease should be based on clinical findings supported by results of laboratory tests. These laboratory tests may consist of either direct identification of *B. burgdorferi* in the patient or demonstration of a serologic response to the organism.

Methods for identifying the presence of *B. burgdorferi* in a patient (e.g., culture, histopathologic examination, antigen detection) generally have poor sensitivity or specificity or both and may require invasive procedures (e.g., a biopsy of the skin) to obtain an appropriate specimen for testing. Isolation of *B. burgdorferi* from a symptomatic patient should be considered diagnostic of Lyme disease. *B. burgdorferi* has been isolated from blood, skin biopsy specimens, cerebrospinal fluid (CSF), myocardial biopsy specimens, and the synovium of patients with Lyme disease. The medium in which *B. burgdorferi* is cultured is expensive, however, and it can take 6 weeks for the spirochete to grow in culture. The best chance of culturing *B. burgdorferi* from a patient is when erythema migrans is present [93], although at this stage of the disease, the diagnosis should be largely clinical. During the later stages of Lyme disease, culture is much less sensitive. In addition, it is necessary for patients to undergo an invasive procedure, such as a biopsy, to obtain appropriate tissue or fluid for culture. Culture is indicated only in rare circumstances.

*B. burgdorferi* has been identified with silver stains (Warthin-Starry or modified Dieterle) and with immunohistochemical stains (with monoclonal or polyclonal antibodies) in skin, synovial, and myocardial biopsy specimens. *B. burgdorferi* can be confused with normal tissue structures, however, or it may be missed because it often is present in low concentrations. Considerable training and experience are needed for skill in identifying spirochetes in tissues. Direct detection of *B. burgdorferi* in tissue is of limited practical value.

Attempts have been made to develop antigen-based diagnostic tests for Lyme disease, but no convincing data indicating the accuracy of any of these tests are available. All of these tests should be considered experimental until additional studies confirm their validity and reproducibility. Assays to detect *B. burgdorferi* antigens in CSF or urine, including the Lyme urine antigen test based on the procedure of Hyde and colleagues [94,95], have poor specificity and poor sensitivity and are not recommended [96].

Tests that use PCR techniques to identify *B. burgdorferi* may be helpful. Results of such tests may be positive for some time after the spirochetes are no longer viable, however. In addition, the risk of false-positive results on PCR assays is great, especially when they are performed in commercial laboratories. If a PCR test is done, it should be performed in a reference laboratory that meets the highest standards of quality control for diagnostic PCR assays [95]. Because of its limited availability, expense, and insufficient evidence of its value in the management of most patients, PCR is at present reserved for special situations [97]. Use of PCR assay may be appropriate in testing of specimens such as synovial tissue or fluid from patients with persistent arthritis after a course of appropriate antibiotic therapy for late Lyme disease; samples of abnormal CSF from patients who are seropositive for antibodies to *B. burgdorferi* and have a neurologic illness that is compatible with, but not typical of, Lyme disease; and skin biopsy specimens from patients who have a localized rash that is consistent with erythema migrans, but have no history of possible exposure or residence in or travel to areas where Lyme disease is endemic [97]. At present, there is insufficient evidence of the accuracy, predictive value, or clinical significance of a PCR test of urine for *B. burgdorferi*, and its use for decisions regarding the management of patients has been strongly discouraged [97].

Because of the limitations of laboratory tests designed to identify directly the presence of *B. burgdorferi* in a patient, the confirmation of Lyme disease in patients without erythema migrans usually is based on the demonstration of antibodies to *B. burgdorferi* in the serum. The normal antibody response to acute infection with *B. burgdorferi* is well described [98]. Specific IgM antibodies appear first, usually 3 to 4 weeks after the infection begins. These antibodies peak after 6 to 8 weeks and subsequently decline. A prolonged elevation of IgM antibodies sometimes is seen, however, even after effective antimicrobial treatment [99]. Consequently, the results of serologic tests for specific IgM antibodies should not be used as the sole indicator of the timing of an infection. Specific IgG antibodies usually appear 6 to 8 weeks after the onset of the infection. These antibodies peak in 4 to 6 months. The IgG antibody titer may decline after treatment, but even after the patient is clinically cured, these antibodies usually remain detectable for many years [100,101].

The immunofluorescent antibody test was the initial serologic test for diagnosing Lyme disease. It requires subjective interpretation and is time-consuming to perform, however, and has largely been replaced by ELISA. The ELISA method may give false-positive results because of cross-reactive antibodies in patients with other spirochetal infections (e.g., syphilis, leptospirosis, relapsing fever), certain viral infections (e.g., varicella), and certain autoimmune diseases (e.g., systemic lupus erythematosus). In contrast to patients with syphilis, patients with Lyme disease do not have positive results on nontreponemal tests for syphilis, such as the Venereal Disease Research Laboratory or rapid plasma reagin. In addition, antibodies directed against bacteria in the normal oral flora may cross-react with antigens of *B. burgdorferi* to produce a false-positive ELISA result.

The first-generation ELISA method uses either whole cells of *B. burgdorferi* or the supernatant of sonicated spirochetes as the antigen. To improve the specificity of the ELISA, new assays have been developed that use less complex fractions of the spirochetes, such as the bacterial membrane, or purified native or recombinant proteins, alone or in combination [97].

Immunoblot (Western blot) analysis for serum antibodies to *B. burgdorferi* also is used as a serologic test for Lyme disease. Although some investigators have

suggested that immunoblot is more sensitive and more specific than ELISA, there is still some debate about its interpretation. Immunoblot is most useful for validating a positive or equivocal ELISA result, especially in patients with a low clinical likelihood of having Lyme disease. For serologic testing for Lyme disease, it is recommended that a sensitive ELISA be performed, and, if results are either positive or equivocal, that a Western blot analysis be done to confirm the specificity of the result [88]. Specimens that give a negative result on a sensitive ELISA do not require immunoblot.

One reason for the poor sensitivity of serologic tests for Lyme disease is that erythema migrans, which is the clinical finding that usually brings patients to medical attention, usually appears within 2 to 3 weeks of onset of infection with *B. burgdorferi*. Antibodies to *B. burgdorferi* often are not detected at this early stage of the disease. The antibody response to *B. burgdorferi* also may be abrogated in patients with early Lyme disease who receive prompt treatment with an effective antimicrobial agent; in these patients, antibodies against *B. burgdorferi* may never develop, at least as a result of that exposure. Most patients with early, disseminated Lyme disease and virtually all patients with late Lyme disease have serum antibodies to *B. burgdorferi*, however. Seropositivity may persist for years even after successful antimicrobial therapy. Ongoing seropositivity, even persistence of IgM, is not a marker of active infection. Likewise, serologic tests should not be used to assess the adequacy of antimicrobial therapy.

Serologic tests for Lyme disease have not been adequately standardized. The accuracy and the reproducibility of currently available serologic tests, especially widely used, commercially produced kits, are poor [102–106]. Use of these commercial diagnostic test kits for Lyme disease would result in a high rate of misdiagnosis. As with any diagnostic test, the predictive value of serologic tests for Lyme disease depends primarily on the probability that the patient has Lyme disease based on the clinical and epidemiologic history and the physical examination (the "pretest probability" of Lyme disease). Use of serologic tests to "rule out" Lyme disease in patients with a low probability of the illness would result in a very high proportion of test results that are falsely positive [107]. Antibody tests for Lyme disease should not be used as screening tests [92,107,108].

With few exceptions, the probability that a patient has Lyme disease would be very low in areas in which Lyme disease is rare. Even in areas with a high prevalence of Lyme disease, patients with only nonspecific signs and symptoms, such as fatigue, headache, and arthralgia, are not likely to have Lyme disease [107,108]. Although such nonspecific symptoms are common in patients with Lyme disease, they are almost always accompanied by more specific objective findings, such as erythema migrans, facial nerve palsy, or arthritis. Even when more accurate tests performed by reference laboratories are available, clinicians should order serologic tests for Lyme disease selectively, reserving them for patients from populations with a relatively high prevalence of Lyme disease who have specific objective clinical findings that are suggestive of Lyme disease, so that the predictive value of a positive result is high [107–109].

Clinicians should realize that even though a symptomatic patient has a positive result on serologic testing for antibodies to *B. burgdorferi*, Lyme disease may not be the cause of that patient's symptoms. In addition to the possibility that it is a false-positive result (a common occurrence), the patient may have been infected with *B. burgdorferi* previously, and the patient's symptoms may be unrelated to that previous infection. As noted earlier, when serum antibodies to *B. burgdorferi* do develop, they may persist for many years despite adequate treatment and clinical cure of the illness [100,101]. In addition, because symptoms never develop in some people who become infected with *B. burgdorferi*, in endemic areas there is a background rate of seropositivity among patients who have never had clinically apparent Lyme disease.

The diagnosis of an infection of the central nervous system (CNS) with *B. burgdorferi* is made by showing the presence of inflammation in the CSF and *Borrelia*-specific intrathecal antibodies [95,110]. Most patients with typical cases of Lyme neuroborreliosis have antibodies to *B. burgdorferi* in serum, and testing for the presence of antibodies in the CSF usually is unnecessary [97]. In some instances, examination of the CSF for antibodies to *B. burgdorferi* may be indicated. Because antibodies to *B. burgdorferi* may be present in the CSF as the result of passive transit through a leaky blood-brain barrier, detection of antibodies in the CSF is not proof of infection of the CNS by the organism. Better evidence of CNS disease is the demonstration of intrathecal production of antibodies; this is accomplished by simultaneously measuring the antibodies in the serum and CSF by ELISA and calculating the "CSF index" [97]. As noted previously, a PCR test of the CSF may be helpful in confirming the diagnosis of CNS Lyme disease [95,97].

A lymphoproliferative assay that assesses the cell-mediated immune response to *B. burgdorferi* has been developed and used as a diagnostic test for Lyme disease. This assay has not been standardized, however, and is not approved by the FDA. The indications for this lymphoproliferative assay are few, if any [97].

The diagnosis of Lyme disease in a pregnant woman should be made in accordance with the currently accepted CDC case definition (see Table 17–1). There is no indication for routine prenatal serologic screening of asymptomatic healthy women. Serosurveys have shown that the seroprevalence rates among pregnant women were comparable with those in the general population [76,77,111] and that asymptomatic seroconversion during pregnancy was unusual [76].

## MANAGEMENT AND TREATMENT

Pediatricians are sometimes confronted with the challenge of how to manage an infant born to a woman who was diagnosed with Lyme disease during her pregnancy. The difficulty arises because of the paucity of evidence that congenital Lyme disease is a clinical problem. In addition, for reasons cited earlier, the diagnosis in the mother often is inaccurate. First, parents should be reassured that there is no evidence that the infant is at increased risk of any problem from maternal Lyme disease. Next, an attempt should be made to ascertain the

accuracy of the diagnosis in the mother; if the mother did not have objective signs of Lyme disease (e.g., erythema migrans) or if the diagnosis was based on nonspecific symptoms (e.g., fatigue, myalgia) and a positive serologic test result, it is likely that the diagnosis is inaccurate.

There is no reason to order serologic tests for Lyme disease in infants who are asymptomatic (even if diagnosis of Lyme disease in the mother is accurate). If such tests are ordered, it is important to remember that if the mother did have Lyme disease and is seropositive, the infant may have passively acquired antibodies from the mother and so may remain seropositive for many months even in the absence of infection. Because of the high frequency of false-positive test results, a positive test result for IgM antibodies against *B. burgdorferi* in an asymptomatic child should be interpreted with a high degree of skepticism.

The choice of antibiotic and the duration of treatment for Lyme disease depend on the stage of the disease that is being treated (Table 17–2). Generally, pregnant women should receive the same treatment as other patients except that use of doxycycline is not recommended during pregnancy [112–114].

## Early Localized Disease

Doxycycline is the drug of choice for children 8 years and older with early localized Lyme disease [112]. Exposure to the sun should be avoided by individuals who are taking doxycycline because a rash develops in sun-exposed areas 20% to 30% of the time. Use of sunscreen may decrease this risk. Amoxicillin is recommended for children younger than 8 years, for pregnant women, and for patients who cannot tolerate doxycycline. For patients allergic to penicillin, alternative drugs are cefuroxime axetil, erythromycin, and azithromycin. Erythromycin and azithromycin may be less effective than other agents. Most experts recommend a 14- to 21-day course of therapy for early localized Lyme disease, although evidence indicates that 10 days of doxycycline constitutes adequate treatment in adults with uncomplicated infection [115].

A prompt clinical response to treatment is usual, with resolution of erythema migrans within several days of initiating therapy. Occasionally, a Jarisch-Herxheimer reaction, which usually consists of an elevated temperature and worsening myalgia, develops shortly after antimicrobial treatment is initiated. These reactions typically last 1 to 2 days and do not constitute an indication to discontinue antimicrobial therapy, and symptoms respond to nonsteroidal anti-inflammatory drugs. Appropriate treatment of erythema migrans almost always prevents development of the later stages of Lyme disease.

## Early Disseminated and Late Disease

Multiple erythema migrans and initial episodes of arthritis should be treated with orally administered antimicrobial agents. If peripheral facial nerve palsy is the only neurologic manifestation of Lyme disease, the patient can be given an oral regimen of antimicrobials. If the facial nerve palsy is accompanied by clinical evidence of CNS involvement (e.g., severe headache, nuchal rigidity), a lumbar puncture should be performed. If there is pleocytosis, parenterally administered antimicrobials should

**TABLE 17–2** Antimicrobial Treatment of Lyme Disease

| |
|---|
| ***Early Disease*** |
| **Localized Erythema Migrans** |
| Doxycycline, 2-4 mg/kg/d twice daily (maximum 100 mg/dose) for 14-21 days (do not use in children <8 yr old), or amoxicillin, 50 mg/kg/d three times a day (maximum 500 mg/dose) for 14-21 days. Preferred alternative agent for patients who cannot take either amoxicillin or doxycycline is cefuroxime axetil, 30 mg/kg/d twice daily (maximum 500 mg/dose) for 14-21 days. Erythromycin and azithromycin are less effective alternatives for patients who cannot take other recommended agents |
| **Neurologic Disease** |
| Isolated seventh cranial nerve or other cranial nerve palsy: Treat as for localized erythema migrans, but for 14-21 days (doxycycline preferred if possible)<br>Meningitis (with or without encephalitis or radiculoneuritis): Ceftriaxone, 50-75 mg/kg once daily (maximum 2 g/dose) for 14-28 days. Alternatives include penicillin G, 200,000-400,000 U/kg/d (maximum 18-24 million U/d) every 4 hr, or cefotaxime 150 mg/kg/d (maximum 2 g/dose) divided every 8 hr for 14-28 days, and oral doxycycline, 4 mg/kg/d twice daily (maximum 200 mg/dose) for 14-21 days |
| **Carditis** |
| First-degree or second-degree heart block: Treat as for localized erythema migrans<br>Third-degree heart block or other evidence of severe carditis: Treat as for meningitis |
| ***Late Disease*** |
| **Arthritis** |
| Doxycycline, 2-4 mg/kg/d twice daily (maximum 100 mg/dose) for 28 days (do not use in children <8 yr old), or amoxicillin, 50 mg/kg/d twice daily (maximum 500 mg/dose) for 28 days. Preferred alternative agent for patients who cannot take either amoxicillin or doxycycline is cefuroxime axetil, 30 mg/kg/d twice daily (maximum 500 mg/dose) for 28 days. For recurrent or persistent arthritis for which oral treatment has failed, either a second course of one of the orally administered agents for 28 days or a course of parenteral treatment for 14-28 days (as for meningitis) is indicated |
| **Neurologic Disease** |
| Treat as for meningitis above for 14-28 days |

be prescribed. Meningitis and recurrent or persistent arthritis also should be treated with parenterally administered antimicrobial agents. Some experts prescribe a second course of an orally administered antimicrobial agent for recurrent or persistent arthritis, however, before using a parenterally administered agent. Nonsteroidal anti-inflammatory drugs are a useful adjunct to antimicrobial therapy for patients with arthritis. Although mild carditis is usually treated orally with either doxycycline or amoxicillin, most experts recommend parenterally administered therapy for severe carditis. Other neurologic manifestations of late Lyme disease (e.g., encephalitis, encephalopathy, polyneuropathy) should be treated with antimicrobials administered parenterally.

The optimal duration of antimicrobial therapy for the various stages of Lyme disease is not well established, but there is no evidence that children with any manifestation of Lyme disease benefit from prolonged (>4 weeks) courses of either orally or parenterally administered antimicrobial agents. Lyme disease, similar to other infections, may trigger a fibromyalgia syndrome that does not respond to additional courses of antimicrobials, but may be managed with symptomatic therapy.

## PROGNOSIS

Attempts to determine the potential impact of gestational Lyme disease on the outcome of the pregnancy have been limited for several reasons [116]. First, the prevalence of Lyme disease among pregnant women, even in highly endemic areas, is low, making it difficult to perform studies with sufficient statistical power. Second, diagnoses of gestational Lyme disease that are based on seropositivity, a history of a tick bite, or even a retrospective clinical history are often unreliable. Finally, because of increased awareness and concern about Lyme disease, it is difficult to find women with suspected gestational Lyme disease who did not receive antimicrobial treatment.

Despite these limitations, *B. burgdorferi* can cross the placenta, presumably during a period of spirochetemia. The frequency and clinical significance of transplacental transmission of *B. burgdorferi* are unclear, however. Although a temporal relationship between Lyme disease during pregnancy and adverse outcomes has been documented, a causal relationship has not been established. The claims for the existence of a congenital Lyme disease syndrome are undermined by the absence of an inflammatory response in fetal tissue, absence of a fetal immunologic response, and lack of a consistent clinical outcome in affected pregnancies. Analysis of the current data indicates that there is no evidence of increased risk of abnormal outcomes with Lyme disease during pregnancy.

It is difficult to conduct high-quality studies of clinical outcome in patients with Lyme disease. On the basis of the available data, the long-term prognosis for adults or children who receive appropriate antimicrobial therapy for Lyme disease, regardless of the stage of the disease, seems to be excellent [117]. The most common reason for a lack of response to appropriate antimicrobial therapy for Lyme disease is misdiagnosis (i.e., the patient actually does not have Lyme disease). In approximately 10% of adults and less than 5% of children with Lyme arthritis, inflammatory joint disease develops that typically affects one knee for months to years and does not respond to antimicrobial therapy. An increased frequency of certain HLA-DR4 alleles has been noted among these patients, and more recent findings suggest that an autoimmune process is involved [118].

## PREVENTION

Reducing the risk of tick bites is one strategy to prevent Lyme disease. In endemic areas, clearing brush and trees, removing leaf litter and woodpiles, and keeping grass mowed may reduce exposure to ticks. Application of pesticides to residential properties is effective in suppressing populations of ticks, but may be harmful to other wildlife and to people. Erecting fences to exclude deer from residential yards and maintaining tick-free pets also may reduce exposure to ticks.

Tick and insect repellents that contain *N,N*-diethyl-*m*-toluamide (DEET) applied to the skin provide additional protection, but most preparations require reapplication every 1 to 2 hours for maximum effectiveness. Serious neurologic complications in children from frequent or excessive application of DEET-containing repellents have been reported, but they are rare, and the risk is low when these products are used according to instructions on the label. Use of products with concentrations of DEET greater than 30% is unnecessary and increases the risk of adverse effects. DEET should be applied sparingly only to exposed skin, but not to a child's face, hands, or skin that is either irritated or abraded. After the child returns indoors, skin that was treated should be washed with soap and water. Permethrin (a synthetic pyrethroid) is available in a spray for application to clothing only and is particularly effective because it kills ticks on contact.

Because most people (approximately 75%) who recognize that they were bitten by a tick remove the tick within 48 hours [23], the risk of Lyme disease from recognized deer tick bites is low—approximately 1% to 3% in areas with a high incidence of Lyme disease. The risk of Lyme disease probably is higher from unrecognized bites (because in those cases the tick feeds for a longer time). A large study of antimicrobial prophylaxis after tick bites among adults found that a single, 200-mg dose of doxycycline was 87% effective in preventing Lyme disease, although the 95% confidence interval around this estimate of efficacy was wide (the lower bound was ≤25%, depending on the method used) [19]. In that study, the only persons in whom Lyme disease developed had been bitten by nymph-stage ticks that were at least partially engorged; the risk of Lyme disease in this group was 9.9% (among recipients of placebo), whereas it was zero for bites by all larval and adult deer ticks.

The expertise to identify the species, stage, and degree of engorgement of a tick—and to assess the degree of risk—is rarely available to people who are bitten. Consequently, routine use of antimicrobial agents to prevent Lyme disease in people who are bitten by a deer tick, even in highly endemic areas, generally is not recommended because the overall risk of Lyme disease is low. Only doxycycline (which is not recommended for children <8 years old) has been shown to be effective in

prophylaxis of Lyme disease [25]. In the unusual instance in which doxycycline prophylaxis is used (e.g., in a nonpregnant patient >8 years old who removes a fully engorged nymph-stage deer tick in an endemic area), only a single dose of doxycycline (200 mg) should be prescribed, and it should be taken with food to minimize nausea.

There is no evidence that pregnant women are at increased risk of Lyme disease after a deer tick bite. The only drug that has been shown to be effective in preventing Lyme disease after a tick bite, doxycycline, is not recommended for use during pregnancy because of its possible effect on the developing fetus. Consequently, antimicrobial prophylaxis is not recommended for pregnant women.

Serologic testing for Lyme disease after a recognized tick bite also is not recommended. Antibodies to *B. burgdorferi* that are present at the time that the tick is removed likely would be due either to a false-positive test result or to an earlier infection with *B. burgdorferi*, rather than to a new infection from the recent bite. Likewise, in this setting the predictive value of a positive result is very low.

Ascertainment of whether the tick is infected, using tests such as PCR, is also not recommended. Although testing ticks with PCR may provide important epidemiologic information, the predictive values for infection of humans of either a positive or a negative PCR test result is unknown. The result may be positive even if only very few organisms are present, and it provides no information about the duration of feeding, a key determinant of the risk of transmission. In addition, the problems of false-positive results owing to contamination with amplification products and false-negative results owing to inhibition of PCR by substances in the sample (e.g., blood) limit the test's validity.

People should be taught to inspect themselves and their children's bodies and clothing daily after possible exposure to ixodid ticks. An attached tick should be grasped with medium-tipped tweezers as close to the skin as possible and removed by gently pulling the tick straight out. If some of the mouth parts remain embedded in the skin, they should be left alone because they usually are extruded eventually; additional attempts to remove them often result in unnecessary damage to tissue and may increase the risk of local bacterial infection.

## RELAPSING FEVER

Relapsing fever is an arthropod-borne zoonosis caused by various *Borrelia* species [10]. There are two forms of relapsing fever. Tick-borne relapsing fever (TBRF), or endemic relapsing fever, is caused by various *Borrelia* species associated with soft ticks of the genus *Ornithodoros*. Louse-borne relapsing fever (LBRF), or epidemic relapsing fever, is caused by *B. recurrentis*, which is associated with the human body louse (*Pediculus humanus*) [10].

The distribution and occurrence of TBRF depend on the enzootic cycle of the transmitting tick vector. In contrast, the distribution and occurrence of LBRF depend on socioeconomic and ecologic factors. LBRF usually occurs in epidemics that are associated with catastrophic events (e.g., war, famine, natural disasters) that result in overcrowding and dissemination of body lice [10]. LBRF is endemic in the highlands of East Africa (Ethiopia, Sudan, Somalia, Chad) and in the South American Andes (Bolivia, Peru). TBRF has been reported worldwide, with the exception of a few areas in the South Pacific. In North America, *B. hermsii* and *B. turicatae* are the major causes of TBRF [11].

LBRF is transmitted when there is contamination of abraded or normal skin with hemolymph of an infected crushed louse. In TBRF, human infection occurs when saliva or coxal fluid containing the *Borrelia* organisms are released in the feeding puncture.

After an incubation period of approximately 7 days (range 4 to $\geq$18 days), the onset of disease is signaled by fever [10]. The fever coincides with large numbers of *Borrelia* organisms in the blood. The relapsing pattern is due to variation of lipoproteins that results in new antigenic variants of major surface lipoproteins and the recurrence of large numbers of *Borrelia* organisms in the blood [11,12]. The most common clinical manifestations of relapsing fever are splenomegaly (41% to 77%), hepatomegaly (17% to 66%), jaundice (7% to 36%), rash (8% to 28%), respiratory symptoms (16% to 34%), and CNS involvement (9% to 30%) [10]. Other complaints include nausea, vomiting, cough, dizziness, and epistaxis [13]. The findings on physical examination may be normal, but tachycardia, tachypnea, jaundice, purpura, or hepatosplenomegaly may be present. The clinical manifestations of LBRF and TBRF are similar, although LBRF is usually associated with a single relapse, whereas multiple relapses are more common with TBRF.

The definitive diagnosis of relapsing fever is established by the demonstration of *Borrelia* organisms in the peripheral blood of febrile patients. In approximately 70% of cases, spirochetes can be seen in the initial blood smear, and the yield increases with multiple smears [14]. Serologic tests are not generally available and, if performed, are of limited diagnostic value because of antigenic variation of strains and the complexity of the relapsing phenomenon. Where available, molecular methods are highly effective in detecting and identifying *Borrelia* species [15].

Several antibiotics, including, tetracyclines, penicillin, ampicillin, erythromycin, and chloramphenicol, are known to be effective for treating relapsing fever [10]. TBRF has an overall case-fatality rate of 2% to 5%, but the rate is greater than 20% in infants younger than 1 year of age [9,10].

In some areas of Africa, relapsing fever during pregnancy is associated with a 30% risk of pregnancy loss and fetal and infant mortality rates of 15% and 44% [12,13]. Common complications of relapsing fever during pregnancy are low birth weight, preterm delivery, spontaneous abortion, and neonatal death. Most pregnancy and perinatal complications have been reported from sub-Saharan Africa, although there are reports from developed countries as well [12]. Pregnant women showed significantly higher densities of spirochetes than nonpregnant women, and a correlation has been seen between density of spirochetes and risk of birth during the attack and risk of complications [16,17].

Maternal-infant transmission of relapsing fever has been reported primarily from sub-Saharan Africa, but cases from

developed countries such as the United States and Israel have also been reported [12]. Transplacental transmission in humans has been established and seems to be the most likely explanation for most of the neonatal cases. In many of these neonatal cases, infections after or during the birth could not be definitively excluded, however [12].

The clinical signs of relapsing fever in the newborn are those of neonatal sepsis and are nonspecific—apathy, vomiting, tachypnea, acidosis, and bleeding tendency. An unusually high concentration of *Borrelia* organisms is found in the peripheral blood smears in affected neonates. The overall mortality in this age group is higher (>40%) than in any other age group [9,12].

CHAPTER 18

# TUBERCULOSIS

**Jeffrey R. Starke ✪ Andrea T. Cruz**

CHAPTER OUTLINE

Tuberculosis is a classic familial disease [1]. The household is the main setting throughout the world for the person-to-person spread of *Mycobacterium tuberculosis*. With the resurgence of tuberculosis in many industrialized nations, issues concerning pregnant women and their children have been reexamined by practitioners of tuberculosis control.

Before 1985, tuberculosis in pregnant women and newborns had become uncommon in the United States. Although specific statistics concerning tuberculosis in pregnancy are not reported, the increase in total tuberculosis cases in the late 1980s and 1990s and the shift in numbers to young adults and children suggested that tuberculosis in pregnancy may become a more prevalent problem [2,3]. In the United States, 6% of cases occur in persons younger than 15 years of age, and almost 40% occur in persons 15 to 44 years old [4,5]. Tuberculosis disproportionately affects minority urban populations because they have very high tuberculosis case rates, a greater relative shift in cases to adults of childbearing age, and generally less access to prenatal care and screening for disease and infection caused by *M. tuberculosis*.

The influence of pregnancy on the occurrence and prognosis of tuberculosis has been discussed and debated for centuries. At various times, pregnancy has been thought to improve, worsen, or have no effect on the prognosis of tuberculosis. This controversy has lost much of its importance since the advent of effective antituberculosis chemotherapy. The greatest areas of debate at present concern the use of chemotherapy to prevent the progression of *M. tuberculosis* infection to tuberculosis during pregnancy and the postpartum period and treatment of exposed infants to prevent the development of serious tuberculosis [6].

## TERMINOLOGY

A practical approach to tuberculosis terminology is to follow the natural history of the disease, which can be divided into three stages: exposure, infection, and disease [7]. *Exposure* implies that the patient has had recent (<3 months) and significant contact with an adult with suspected or confirmed contagious pulmonary tuberculosis. An infant born into a family in which an adult has active tuberculosis would be in the exposure stage. In this stage, the infant's tuberculin skin test is negative, the chest radiograph result is normal, and the infant is free of signs and symptoms of tuberculosis. It is impossible to know whether a young child in the exposure stage is truly infected with *M. tuberculosis* because the development of delayed-type hypersensitivity to a tuberculin skin test may take 3 months after the organisms have been inhaled.

*Infection* with *M. tuberculosis* is present if an individual has a positive tuberculin skin test or interferon-γ release assay result, but lacks signs or symptoms of tuberculosis. In this stage, findings on the chest radiograph either are normal or reveal only granuloma or calcification in the lung parenchyma or regional lymph nodes. The purpose of treating *M. tuberculosis* infection is to prevent future disease. In newborns, the progression from infection to disease can occur very rapidly—within several weeks to months. Of untreated infants with a positive tuberculin skin test, 40% progress to disease.

DOI: 10.1016/B978-1-4160-6400-8.00018-3

Tuberculosis *disease* occurs if signs or symptoms or radiographic manifestations caused by *M. tuberculosis* become apparent. Because 25% to 35% of children with tuberculosis have extrapulmonary involvement, a thorough physical examination, in addition to a high-quality chest radiograph, is essential to rule out disease [7]. Genitourinary tuberculosis in women often causes only subtle symptoms until it is far advanced. Initially, 10% to 20% of immunocompetent adults and children with the disease have a negative tuberculin skin test result, usually because of immunosuppression from tuberculosis itself. The rate of negative skin test results with disease from *M. tuberculosis* is much higher in newborns and small infants, however, especially if they have life-threatening forms of tuberculosis, such as disseminated (miliary) disease or meningitis.

## MYCOBACTERIOLOGY

Mycobacteria are nonmotile, non–spore-forming pleomorphic, weakly gram-positive rods that are 1 to 5 μm long, usually slender, and slightly curved. *M. tuberculosis* may appear beaded or clumped. The cell wall constituents of mycobacteria determine their most striking biologic properties. The cell wall is composed of 20% to 60% lipids bound to proteins and carbohydrates. These and other properties make mycobacteria more resistant than most other bacteria to light, alkali, acid, and bactericidal activity of antibodies. Growth of *M. tuberculosis* is slow, with a generation time of 12 to 24 hours on solid media.

The hallmark of mycobacteria is acid-fastness, the capacity to form stable mycolate complexes with certain aryl methane dyes that are not removed even by rinsing with 95% ethanol plus hydrochloric acid. The cells appear red when stained with carbol fuchsin (Ziehl-Neelsen or Kinyoun stains) or purple when stained with crystal violet or exhibit yellow-green fluorescence under ultraviolet light when stained with Truant auramine-rhodamine stain. Truant auramine-rhodamine stain is considered the most sensitive stain, especially when small numbers of organisms are present. Approximately 10,000 cells/mm$^3$ must be present in a sample for them to be seen in an acid-fast stained smear.

Identification of mycobacteria depends on their staining properties and their biochemical, metabolic, and growth characteristics. *M. tuberculosis* also can be distinguished from nontuberculous mycobacteria by high-power liquid chromatography. Mycobacteria are obligate aerobes with simple growth requirements. *M. tuberculosis* can grow in classic media whose essential ingredients are egg yolk and glycerin (Löwenstein-Jensen or Dorset media) or simple synthetic media (Middlebrook 7H10 agar, Tween-albumin). Isolation on solid media takes 2 to 6 weeks, followed by another 2 to 4 weeks for drug-susceptibility testing.

More rapid isolation (7 to 21 days) can be achieved using synthetic liquid medium in an automated radiometric system; the most common is BACTEC (Becton-Dickinson, Towson, MD). A specimen is inoculated into a bottle of medium containing carbon-14–labeled palmitic acid as a substrate. As mycobacteria metabolize the palmitic acid, carbon dioxide-14 accumulates in the head space of the bottle, where radioactivity can be measured. Because bottles are often analyzed in series by repetitive needle aspiration in an automated, single-needle system, cross-contamination leading to a false-positive culture can occur. Drug susceptibility testing can be performed on the same system using bottles with antimicrobial agents added to the medium. In this radiometric system, identification and drug-susceptibility testing often can be completed in 2 to 3 weeks, depending on the concentration of organisms in the patient sample.

More recently, a novel system has been developed wherein the culture and susceptibility are performed simultaneously in liquid media. This system—microscopic-observed drug susceptibility (MODS)—can provide results in 7 days [8,9]. MODS methodology also has been effective for children, showing increased yield over traditional culture techniques (87% versus 55%) and decreased time to positive cultures (10 days versus 24 days) [10].

It is often difficult to isolate *M. tuberculosis* from infants and toddlers with tuberculosis [11,12]. Infants and children with pulmonary tuberculosis rarely produce sputum, the usual culture material for adults. The preferred source of culture for children is a gastric aspirate, performed early in the morning before the stomach has been emptied of the respiratory secretions swallowed overnight. For older children, the culture yield from gastric aspirates obtained on 3 consecutive mornings is 20% to 40% [13]. The yield from infants is usually higher, up to 75% [14]. For many infants with congenital pulmonary tuberculosis, *M. tuberculosis* can be cultured from a tracheal aspirate because of the numerous organisms in the lungs. Induced sputum cultures, obtained by nasopharyngeal suctioning after administration of albuterol, nebulized oxygen, and chest percussion, are safe and effective in infants 1 month old. The yield for one induced sputum culture is similar to the yield of three gastric aspirate specimens, specimens obtained by induced sputum collection are more likely to be acid-fast positive, and the specimens may be obtained more readily in the outpatient setting [15].

Several types of nucleic acid amplification have been developed to detect *M. tuberculosis* in patient samples. The main form of nucleic acid amplification studied in children with tuberculosis is polymerase chain reaction (PCR), which uses specific DNA sequences as markers for microorganisms. Various PCR techniques, most using the mycobacterial insertion element IS6110 as the DNA marker for *M. tuberculosis* complex organisms, have a sensitivity and specificity of greater than 90% compared with sputum culture for detecting pulmonary tuberculosis in adults. Test performance varies, however, even among reference laboratories. The test is expensive and requires fairly sophisticated equipment and scrupulous technique to avoid cross-contamination of specimens.

Use of PCR in childhood tuberculosis has been limited. Compared with a clinical diagnosis of pulmonary tuberculosis in children, sensitivity of PCR ranges from 25% to 83%, and specificity ranges from 80% to 100% [16]. PCR detection rates are higher for specimens positive for acid-fast bacilli smear (100% versus 76%) [17,18]. PCR of gastric aspirates may be positive in a recently infected child even when the chest radiograph is normal,

showing the occasional arbitrariness of the distinction between *M. tuberculosis* infection and disease in children. PCR may have a useful but limited role in evaluating children for tuberculosis. A negative PCR never eliminates tuberculosis as a diagnostic possibility, and a positive result does not confirm it. The major use of PCR would be in evaluating children with significant pulmonary disease when the diagnosis is not established readily on clinical or epidemiologic grounds.

PCR may be particularly helpful in evaluating immunocompromised children with pulmonary disease, especially children with human immunodeficiency virus (HIV) infection, although published reports of its performance in such children are lacking. PCR also may aid in confirming the diagnosis of extrapulmonary tuberculosis, although few data have been published. In one study, PCR of cerebrospinal fluid in children with suspected tuberculous meningitis showed a sensitivity of 76% and a specificity of 89% [19]. Finally, PCR assays are now being designed to amplify regions of the bacterial genome where mutations are known to confer resistance to commonly used medications; this has the potential to provide drug-resistance profiles even on patients whose cultures remain negative [20]. There is concern, however, that genotypes and phenotypes may not overlap entirely [21]. No information has been published concerning the accuracy of PCR or other techniques of nucleic acid amplification in samples from pregnant women or neonates with congenital or postnatally acquired tuberculosis.

Relatedness of strains of *M. tuberculosis* was determined in the past by analysis of bacteriophages, a cumbersome and difficult task. A newer technique, restriction fragment length polymorphism analysis of mycobacterial DNA, has become an accurate and powerful tool for determining strain relatedness [22,23]. It is used frequently in some communities and may help determine if an infant with tuberculosis has true congenital infection or was infected by another source.

## EPIDEMIOLOGY

Tuberculosis is the leading infectious disease in the world [24]. It is estimated that 2 billion persons are infected with *M. tuberculosis*, 9 million develop tuberculosis disease annually, and 2 million die with tuberculosis each year [24]. In the developing world, the World Health Organization (WHO) estimates that there are 1.3 million cases of tuberculosis and 400,000 tuberculosis-related deaths annually among children younger than 15 years of age. In most developing countries, the highest rates of tuberculosis occur among young adults. Although much attention has been given more recently to the growing number of children orphaned in developing countries by their parents' deaths from HIV-related illnesses, many orphans also are being created by tuberculosis.

In the United States from 1953-1984, the incidence of tuberculosis disease declined an average of 5% per year. From 1985-1992, there was a 20% increase in total cases of tuberculosis in the United States and a 40% increase in tuberculosis cases among children [25]. Most experts cite four major factors contributing to this increase: (1) the coepidemic of HIV infection [26], which is the strongest risk factor known for development of tuberculosis disease in an adult infected with *M. tuberculosis* [27]; (2) the increase in immigration of people to the United States from countries with a high prevalence of tuberculosis, enlarging the pool of infected individuals [28,29]; (3) the increased transmission of *M. tuberculosis* in congregate settings, such as jails, prisons, hospitals, nursing homes, and homeless shelters; and (4) the general decline in tuberculosis-related public health services and access to medical care for the indigent in many communities [30]. In 2007, the approximately 13,300 cases of tuberculosis in the United States represented a 50% decline from the peak number of cases in 1992 [31]. The average annual percent decline has slowed, however, from 7.3% per year in 1993-2000 to 3.8% per year in 2000-2007 [31].

In the early 20th century in the United States, when tuberculosis was more prevalent, the risk of becoming infected with *M. tuberculosis* was high across the entire population. Currently, tuberculosis has retreated into fairly well-defined pockets of high-risk individuals, such as foreign-born persons from high-prevalence countries, persons who travel to high-prevalence countries, inmates of correctional institutions, illicit drug users, unprotected health care workers who care for high-risk patients, migrant families, homeless persons, and anyone likely to encounter people with contagious tuberculosis. One must distinguish the risk factors for becoming infected with *M. tuberculosis* from factors that increase the likelihood that an infected individual will develop disease. Age, immunocompromised status, and recent infection with *M. tuberculosis* are the major risk factors for progression of infection to disease.

Although tuberculosis occurs throughout the United States, cases are disproportionately reported from large urban areas. Cities with populations exceeding 250,000 account for only 18% of the U.S. population, but almost 50% of tuberculosis cases in the United States. Among U.S.-born persons, tuberculosis disproportionately affects African Americans, whose rates of tuberculosis disease remain 8.5 times the rates seen in whites born in the United States [31,32].

The number of tuberculosis cases in the United States is increasing among foreign-born persons from countries with a high prevalence of tuberculosis. The percentage of total cases of tuberculosis in the United States that occurs in foreign-born individuals increased from 22% in 1986 to 59% in 2007, and foreign-born individuals have a 9.7 times higher rate of tuberculosis than individuals born in the United States [31]. In addition, 85% of cases of multidrug-resistant (MDR) tuberculosis are seen in foreign-born individuals [31]. In previous estimates, two thirds of foreign-born individuals with tuberculosis were younger than 35 years when entering the United States, and in many cases, their disease could have been prevented if they had been identified as infected after immigration and given appropriate treatment for *M. tuberculosis* infection.

Until very recently, new immigrants to the United States older than 15 years of age were required to have a chest radiograph but no tuberculin skin test to detect asymptomatic infection; children younger than 15 years old received no tuberculosis testing as part of immigration

[33]. This policy ignored a huge reservoir of future tuberculosis cases. Studies have estimated that 30% to 50% of the almost 1 million annual new immigrants to the United States are infected with *M. tuberculosis* [29]. Foreign-born women and adolescents of childbearing age should be one group targeted for appropriate tuberculosis screening and prevention [34]. There are data suggesting that the current U.S. Centers for Disease Control and Prevention (CDC) and American Thoracic Society (ATS) policies on targeted screening of immigrants [35] would fail to prevent most cases [36]. A more effective strategy to decrease tuberculosis in the United States may be to expand treatment programs in countries from which immigrants originate [37].

Another factor that has had a great impact on tuberculosis case rates in the United States has been the epidemic of HIV infection [27]. The proportion of women with HIV infection is increasing; the population demographic in which HIV is most rapidly spreading is persons of reproductive age (13 to 44 years old), who accounted for 73% of newly diagnosed cases in 2006 [38]. Because the risk factors for HIV infection intersect with risk factors for tuberculosis, the number of coinfected women is expected to increase [39–41]. Approximately 16% of tuberculosis patients 25 to 44 years old in the United States are also HIV-seropositive [42]. In most locales experiencing increases in tuberculosis cases, the demographic groups with the greatest tuberculosis morbidity rates are the same as those with high morbidity rates from HIV infection. HIV-infected persons with a reactive tuberculin skin test develop tuberculosis at a rate of 5% to 10% per year compared with a historical average of 5% to 10% for the lifetime of an immunocompetent adult. There is controversy concerning the infectiousness of adults with HIV-associated pulmonary tuberculosis. Although some studies have indicated dually infected adults are as likely as non–HIV-infected adults with tuberculosis to infect others, some studies have shown less transmission from HIV-infected adults [43].

The current epidemiology of tuberculosis in pregnancy is unknown. From 1966-1972, the incidence of tuberculosis during pregnancy at New York Lying-In Hospital ranged from 0.6% to 1% [44]. During this time, 3.2% of the patients with culture-proven pulmonary tuberculosis were first diagnosed during pregnancy, a rate equal to that of nonpregnant women of comparable age. Only two series of pregnant women with tuberculosis have been reported from the United States in the past 2 decades [45,46], and two series have been reported from the United Kingdom [47,48]. In the latter two series, diagnosis was delayed in many women with extrapulmonary manifestations of tuberculosis. Increased risk of tuberculosis is most striking for foreign-born women, who have high rates of tuberculosis infection, and poor minority women.

In the United States, almost 40% of tuberculosis cases in minority women occur in women younger than 35 years. Approximately 80% of cases of tuberculosis infection and disease among children in the United States occur in minority populations [25,49]. Most of these cases occur after exposure to an ill family member. In all populations, whether the disease incidence is high or low, tuberculosis infection and disease tend to occur in clusters, often centered on the close or extended family, meaning that minority newborns are at greatly increased risk of congenital and postnatally acquired tuberculosis infection and disease.

# TUBERCULOSIS IN PREGNANCY

## PATHOGENESIS

The pathogenesis of tuberculosis infection and disease during pregnancy is similar to the pathogenesis for nonpregnant individuals [50,51]. The usual portal of entry for *M. tuberculosis* is the lung through inhalation of infected droplet nuclei discharged by an infectious individual. The inoculum of organisms necessary to establish infection is unknown, but is probably less than 10 [52]. When tubercle bacilli are deposited in the lung, they multiply in the nonimmune host for several weeks. This uninhibited replication usually produces no symptoms, but a patient may experience low-grade fever, cough, or mild pleuritic pain.

Shortly after infection, some organisms are carried from the initial pulmonary focus within macrophages to the regional lymph nodes [53]. From there, organisms enter lymphatic and blood vessels and disseminate throughout the body; the genitalia, the endometrium, and, if the woman is pregnant, the placenta may be seeded [54]. By 1 to 3 months after infection, the host usually develops cell-mediated immunity and hypersensitivity to the tubercle bacillus, reflected by the development of a reactive tuberculin skin test [55]. As immunity develops, the primary infection in the lung and foci in other organs begin to heal through a combination of resolution, fibrosis, and calcification [56]. Although walling-off of these foci occurs, viable tubercle bacilli persist. If the host later becomes immunosuppressed, these dormant bacilli may become active, leading to "reactivation" tuberculosis [57].

There are two major ways that tuberculosis infection in the mother can lead to infection of the fetus in utero. If dissemination of organisms through the blood and lymphatic channels occurs during pregnancy, the placenta may be infected directly. This can occur either during the asymptomatic dissemination that is part of the mother's initial infection or during pulmonary, miliary, or disseminated tuberculosis disease in the mother [58–72]. Miliary tuberculosis in women can arise from a long-standing dormant infection, but more often complicates a recent infection (Fig. 18–1). Infection with *M. tuberculosis* that occurs during pregnancy, as opposed to dormant infection that occurred before the pregnancy, probably poses a greater risk to the fetus. This is a major reason why pregnant women with new onset of *M. tuberculosis* infection usually should be treated carefully during the pregnancy; delay could result in disease in the mother, the infant, or both.

The second mechanism by which a fetus can become infected with *M. tuberculosis* is directly from established genitourinary tuberculosis in the mother. Genital tuberculosis is most likely to start around the time of menarche and can have a very long and relatively asymptomatic course. The fallopian tubes most often are involved

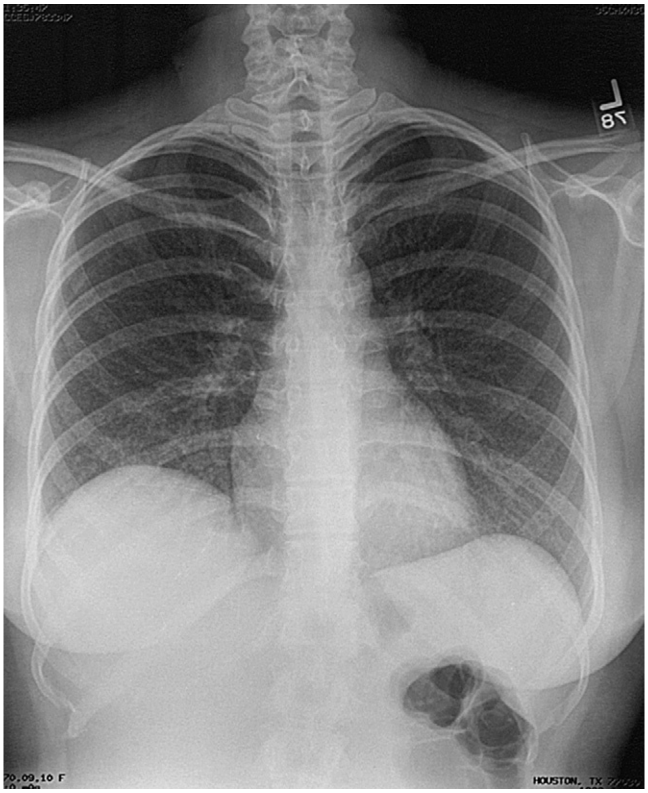

**FIGURE 18–1** Chest radiograph from the mother of the infant shown in Figure 18–2. This radiograph reveals early miliary tuberculosis.

(in 90% to 100% of women), followed by the uterus (50% to 60%), ovaries (20% to 30%), and cervix (5% to 15%) [44,54]. Sterility often is the presenting complaint of tuberculosis endometritis, which diminishes the likelihood of congenital tuberculosis occurring [73,74]. One series from India reported that 28% of women seeking therapy for infertility had genital tuberculosis [75]. Findings on hysterosalpingography of beaded or nonpatent fallopian tubes or irregular uterine filling defects may suggest the diagnosis [75a]. If infection of the placenta occurs, it results more frequently from disseminated tuberculosis in the mother than from a local endometritis. Tuberculous endometritis can lead to congenital infection of the newborn, however [54,76–79]. Tuberculosis in the mother as a complication of in vitro fertilization has been described [80].

## EFFECT OF PREGNANCY ON TUBERCULOSIS

Over the past 2 millennia, medical opinions regarding the interaction of pregnancy and tuberculosis have varied considerably. Hippocrates believed that pregnancy had a beneficial effect on tuberculosis, a view that persisted virtually unchallenged well into the 19th century [81]. In 1850, Grisolle reported 24 cases of tuberculosis that developed during pregnancy [82]. In all patients, the progression of tuberculosis during pregnancy was more severe than that usually seen in nonpregnant women of the same age. Shortly thereafter, several other articles were published that implied that pregnancy had a deleterious effect on tuberculosis. This view gained so much support that by the early 20th century, the practice of induced abortion to deal with the consequences of tuberculosis during pregnancy became widely accepted.

The opinion that pregnancy had a deleterious effect on tuberculosis predominated until the late 1940s. In 1943, Cohen [83] detected no increased rate of progression of tuberculosis among 100 pregnant women with abnormal chest radiograph results. In 1953, Hedvall [82] presented a comprehensive review of published studies concerning tuberculosis in pregnancy. He cited studies totaling more than 1000 cases that reported deleterious effects of pregnancy on tuberculosis. He discovered a nearly equal number of reported cases, however, in which a neutral or favorable relationship between pregnancy and tuberculosis was observed. In his own study of 250 pregnant women with abnormal chest radiograph results thought to be due to tuberculosis, he noted that 9% improved, 7% worsened, and 84% remained unchanged during pregnancy. During the first postpartum year, 9% improved, 15% worsened, and 76% were stable. Cromie [84] noted that 31 of 101 pregnant women with quiescent tuberculosis experienced relapse after delivery. Of the 31 relapses, 20 occurred in the 1st postpartum year.

Several other investigators observed the higher risk of relapse during the puerperium. Several theories were proposed to explain this phenomenon, including postpartum descent of the diaphragm, nutritional stress of pregnancy and lactation, insufficient sleep for the new mother, rapid hormonal changes, and depression in immunity in late pregnancy and postpartum. A similar number of other studies failed to support an increased risk of progression of tuberculosis in the postpartum period, however [85–89].

Cohen's study [85] failed to show an increase in activity of tuberculosis during pregnancy or any postpartum interval. Rosenbach and Gangemi [87] and Cohen and colleagues [85] showed that only 9% to 13% of women with long-standing tuberculosis had progression of disease during the pregnancy or first postpartum year, a rate thought to be comparable to that in nonpregnant women. Few of these studies had adequate control populations. From all the studies reported, it became clear that the anatomic extent of disease, the radiographic pattern, and the susceptibility of the individual patient to tuberculosis were more important than pregnancy itself in determining the course and prognosis of the pregnant woman with tuberculosis.

The controversy concerning the effect of pregnancy or the postpartum period on tuberculosis has lost most of its importance with the advent of effective chemotherapy [90,91]. With adequate treatment, pregnant women with tuberculosis have the same excellent prognosis as nonpregnant women. Several studies documented no adverse effects of pregnancy, birth, postpartum period, or lactation on the course of tuberculosis in women receiving chemotherapy [92,93].

Most studies have dealt with the risk of reactivation of tuberculosis among women with abnormal chest radiograph results but no evidence of active tuberculous lesions. It is unclear if women with asymptomatic *M. tuberculosis* infection but no radiographic findings are at increased risk of developing tuberculosis during pregnancy or the postpartum period. In 1961, Pridie and Stradling [94]

found that the incidence of pulmonary tuberculosis among pregnant women was the same as in the nonpregnant female population of the area. From 1966-1972, Schaefer and associates [44] found that the annual pulmonary tuberculosis case rate among pregnant women in New York Lying-In Hospital was 18 to 29 per 100,000 population, comparable to the incidence of tuberculosis during the same period in women of childbearing age in all of New York City. Although no definitive study has been reported, it seems unlikely that progression from asymptomatic *M. tuberculosis* infection to tuberculosis disease is accelerated during pregnancy or the postpartum period.

## EFFECT OF TUBERCULOSIS ON PREGNANCY

In the prechemotherapy era, active tuberculosis at an advanced stage carried a poor prognosis for the mother and the child. Schaefer and associates [44] reported that the infant and maternal mortality rates from untreated tuberculosis were 30% to 40%. Mortality rates for infants with congenital tuberculosis remain greater than 20% in some more recent series [95], and all-cause mortality is threefold higher in infants born to HIV-infected mothers with tuberculosis [96]. The incidence of congenital tuberculosis parallels the incidence in childbearing women, and increased rates of tuberculosis in infants have been noted in many regions [97].

One study from Norway showed a higher incidence of toxemia, postpartum hemorrhage, and difficult labor in mothers with untreated tuberculosis compared with control subjects [98]. The incidence of miscarriage was almost 10 times higher in the tuberculous mothers, but there was no significant difference in the rate of congenital malformations for children born to mothers with and without tuberculosis. Another study reported an incidence of prematurity ranging from 23% to 64%, depending on the severity of tuberculosis in the mother, for infants born to untreated mothers in a tuberculosis sanitarium [99].

One series compared the clinical courses of 111 pregnant women with treated pulmonary tuberculosis with controls who either had tuberculosis and were not pregnant or were pregnant and did not have tuberculosis. There were no differences in gestational duration, preterm labor, or other pregnancy complications between cases and controls if the women received adequate therapy [100]. Another series reported that maternal extrapulmonary tuberculosis, aside from cervical lymphadenopathy, was associated with higher rates of prenatal hospitalization and lower infant birth weights [101]. Most experts now believe, however, that with proper treatment of a pregnant woman with tuberculosis, the prognosis of the pregnancy should not be affected adversely by the presence of tuberculosis. Because of the excellent prognosis for the mother and the child, the recommendation for therapeutic abortion has been abandoned.

## SCREENING FOR TUBERCULOSIS IN PREGNANCY

For all pregnant women, the history obtained at an early prenatal visit should include questions about a previously positive tuberculin skin test or interferon-γ release assay result, previous treatment for *M. tuberculosis* infection or disease, current symptoms compatible with tuberculosis, and known exposure to other adults with the disease [35,102]. Membership in a high-risk group is a sufficient reason for a tuberculin skin test. For many high-risk women, prenatal or peripartum care represents their only contact with the health care system, and the opportunity to test them for tuberculosis infection or disease should not be lost. Some experts believe that all pregnant women should receive a tuberculin skin test [103]. Most experts believe, however, that only women with specific risk factors for *M. tuberculosis* infection or disease should be tested [35]. Women coinfected with HIV and *M. tuberculosis* may show no reaction to a tuberculin skin test. Pregnant women with high risk for or with known HIV infection should have a thorough investigation for tuberculosis.

Changes in the interpretation of the Mantoux tuberculin skin test have been promoted by the CDC, ATS, and American Academy of Pediatrics [35]. The rationale for using different sizes of induration as representing a positive result in different populations has been discussed thoroughly in many publications. The current recommendation is that for individuals at the highest risk of having *M. tuberculosis* infection progress to tuberculosis—contacts to adults with infectious tuberculosis, patients with an abnormal chest radiograph or clinical evidence of tuberculosis, or persons with HIV infection or other condition associated with an immunocompromised state—a Mantoux tuberculin skin test reaction of at least 5 mm is classified as positive, indicating infection with *M. tuberculosis*. For other high-risk groups, a reaction of at least 10 mm is positive. For all other persons deemed at low risk for tuberculosis, a reaction of at least 15 mm is positive.

This classification scheme depends on the ability and willingness of the family and health care provider to develop a thorough epidemiologic history for tuberculosis exposures and risk. It also depends on accurate interpretation of the skin test. One study implied that pediatricians tend to underread induration in tuberculin skin tests [104], and there is much variability in skin test interpretation by patients and health care workers [105].

There have been no studies to verify whether the classification scheme for the Mantoux tuberculin skin test is valid in pregnant women, but there is no reason to suspect otherwise [106,107]. The effect of pregnancy on tuberculin hypersensitivity as measured by the tuberculin skin test is controversial [108]. Some studies have shown a decrease in in vitro lymphocyte reactivity to purified protein derivative during pregnancy [109]. In vivo studies using patients as their own controls have shown no effect of pregnancy on cutaneous delayed hypersensitivity to tuberculin [110,111]. Most experts believe the tuberculin skin test by the Mantoux technique is valid throughout pregnancy. There is no evidence that the tuberculin skin test has adverse effects on the pregnant mother or fetus or that skin testing reactivates quiescent foci of tuberculosis infection [112].

Whole-blood interferon-γ release assays have been introduced in an attempt to address some of the limitations of the Mantoux tuberculin skin test. Interferon-γ release assay measures interferon-γ response after

challenge with antigens that are not shared with antigens in *Mycobacterium avium* complex and the bacille Calmette-Guérin (BCG) vaccine. The advantages are that the test should theoretically be more specific to tuberculosis than the tuberculin skin test; it requires only one health care encounter; and because the test is done in vitro, there is no risk of the boosting phenomenon [113]. No controlled studies to date have evaluated the efficacy of interferon-γ release assays in pregnancy or in infants.

One of the most difficult problems in the interaction of tuberculosis and pregnancy is deciding whether a pregnant woman with *M. tuberculosis* infection should receive immediate treatment, or whether the treatment should be postponed until after the infant is delivered [114]. Not all infected individuals have the same chance of developing tuberculosis during a short period of time. Individuals who were infected remotely (>2 years previously) have a low chance of developing tuberculosis during a given 9-month period. Individuals who have been infected more recently, particularly if their infection is discovered during a contact investigation of an adult with active tuberculosis, are at much higher risk; about half of the lifetime risk of progression of infection to disease occurs during the first 1 to 2 years after infection. Other vulnerable adults, particularly adults coinfected with HIV, also are at greatly increased risk of having progression of infection to disease.

Treatment for tuberculosis infection should be initiated during pregnancy if the woman likely has been infected recently (especially in the setting of a contact investigation of a recently diagnosed case) or she is at increased risk of rapid development of tuberculosis. Although isoniazid (INH) is not thought to be teratogenic, some experts recommend waiting until the second trimester of pregnancy to begin treatment. Patient adherence to INH treatment for tuberculosis infection seems to be very low if the initiation of treatment is delayed until after the child is delivered. The reason for this low adherence is unclear, but several problems include the perception of nonimportance because a treatment delay of many months is allowed, transfer of care from one segment of the health care system to another, and, perhaps, the lack of reinforcement by health care professionals concerning the importance of the treatment.

One retrospective series indicated that women who were newly diagnosed with tuberculosis infection were more likely to be referred to specialty clinics and start therapy, but completion rates for the cohort as a whole were less than 10% [115]. Although screening and treatment of high-risk pregnant women may seem to be an effective strategy to prevent future cases of tuberculosis, it has not yet been shown that this strategy is successful in the U.S. health care system [116].

Routine chest radiography is not advisable as a screening tool for pregnant women because the prevalence of tuberculosis disease remains fairly low [117,118]. With appropriate shielding, pregnant women with positive tuberculin skin test results should have chest radiographs to rule out tuberculosis [119]. In addition, a thorough review of systems and physical examination should be done to exclude extrapulmonary tuberculosis.

# CONGENITAL TUBERCULOSIS

## TUBERCULOSIS IN THE MOTHER

The clinical manifestations of tuberculosis in a pregnant woman generally are the same as the manifestations in nonpregnant individuals. The most important determinants of the clinical presentation are the extent and anatomic location of disease. In one series of 27 pregnant and postpartum women with pulmonary tuberculosis, the most common clinical findings were cough (74%), weight loss (41%), fever (30%), malaise and fatigue (30%), and hemoptysis (19%) [46]. Almost 20% of patients had no significant symptoms; other studies also have found less significant symptoms in pregnant women with tuberculosis [45]. The tuberculin skin test result was positive in 26 of 27 patients. The diagnosis was established in all cases by culture of sputum for *M. tuberculosis*. Sixteen of the patients in this series had drug-resistant tuberculosis; their clinical course was marked by more extensive pulmonary involvement, a higher incidence of pulmonary complications, longer sputum conversion times, and a higher incidence of death.

In other series, 5% to 10% of pregnant women with tuberculosis have had extrapulmonary disease, a rate comparable with nonpregnant women of the same age [45]. Delay in diagnosis has been associated with extrapulmonary forms of tuberculosis or nonspecific symptoms [48]. In some regions of the developing world, tuberculosis (often with HIV coinfection) accounts for 25% of nonobstetric maternal mortality, and mothers coinfected with HIV and tuberculosis have a twofold increased risk of postpartum death compared with mothers without coinfection [120]. In one series of pregnant women coinfected with HIV and tuberculosis, 29% of postpartum cases were diagnosed in the first 2 weeks after delivery [96], indicating that these women likely had subclinical disease late in pregnancy.

Although the female genital tract may be the portal of entry for a primary tuberculosis infection, more often infection at this site originates by continuity from an adjacent focus of disease or by blood-borne seeding of the fallopian tubes [73]. Progression of disease usually is by descent in the genital tract. Mucosal ulceration within the fallopian tube develops, and pelvic adhesions occur frequently. Many patients are asymptomatic. The most common complaints are sterility and menstrual irregularity with menorrhagia or amenorrhea. These findings greatly diminish the likelihood of congenital tuberculosis. Other, less frequent signs and symptoms include lower abdominal pain and tenderness, weight loss, fever, and night sweats. Diagnosis in a nonpregnant woman is usually established by culture and histologic examination of tissue recovered after uterine curettage. The highest recovery rates of *M. tuberculosis* are obtained from scrapings obtained just before or during menstruation.

Tuberculosis mastitis is very rare in the United States, but occurs almost exclusively in women of childbearing age [121–123]. The most common finding is a single breast mass, with or without a draining sinus. Nipple retraction and peau d'orange skin changes suggestive of carcinoma also may be present. The ipsilateral axillary lymph nodes usually are enlarged. Diagnosis is confirmed

by biopsy of the mass or axillary node and culture of the tissue for *M. tuberculosis*. Radiographic findings are often nonspecific [124]. Transmission of *M. tuberculosis* to the infant through breast milk is exceedingly rare, if it occurs at all.

## ROUTES OF TRANSMISSION

Tuberculosis in the neonate can be either truly congenital (i.e., acquired in utero) or truly neonatal (i.e., acquired early in life from the mother, members of the family, friends, or caretakers). Each of these two kinds of perinatal tuberculosis may be subdivided. *Congenital tuberculosis* can be acquired in three ways: (1) from the infected placenta via the umbilical vein, (2) by inhalation of infected amniotic fluid, and (3) by ingestion of infected amniotic fluid. *Neonatal tuberculosis* can be acquired in four ways: (1) by inhalation of infected droplets, (2) by ingestion of infected droplets, (3) by ingestion of infected milk (theoretical), and (4) by contamination of traumatized skin or mucous membranes.

It is not always possible to ascertain the route of infection in a particular neonate, and with effective chemotherapy at hand, it is not essential for the care of the infant. It is important, however, to try to identify the source of infection so that the person infecting the infant can be treated, and further transmission can be prevented [125].

The potential modes of inoculation of the fetus or newborn with *M. tuberculosis* from the mother are shown in Table 18–1 [126]. Infection of the fetus through the umbilical cord has been rare, with less than 350 cases reported in the English-language literature [127]. Mothers of these infants frequently have tuberculous pleural effusion, meningitis, or disseminated disease during pregnancy or soon after [61,64,66,69,128]. In some series of congenital tuberculosis, fewer than 50% of the mothers were known to have tuberculosis at the time of delivery and beginning of symptoms in the newborn [129,130]. In most of these cases, diagnosis of the child led to the discovery of the mother's tuberculosis.

The intensity of lymphohematogenous spread during pregnancy is one of the factors that determines if congenital tuberculosis will occur. Hematogenous dissemination in the mother leads to infection of the placenta with subsequent transmission of organisms to the fetus. *M. tuberculosis* has been shown in the decidua, amnion, and chorionic villi of the placenta. The organisms also have been shown to reach the placenta through direct extension from a tuberculous salpingeal tube. Even massive involvement of the placenta with tuberculosis does not always give rise to congenital tuberculosis, however [131]. It is unclear if the fetus can be infected directly from the mother's bloodstream without a caseous lesion forming first in the placenta, although this phenomenon has been shown in experimental animal models [132].

**TABLE 18–1** Modes of Inoculation of the Fetus or Newborn with *Mycobacterium tuberculosis*

| Maternal Focus | Mode of Spread |
|---|---|
| Placentitis | Hematogenous (umbilical vessel) |
| Amniotic fluid | Aspiration |
| Cervicitis | Direct contact |
| Pneumonitis | Airborne (postnatal) |

In hematogenous congenital tuberculosis, the organisms reach the fetus through the umbilical vein. If bacilli infect the liver, a primary focus develops with involvement of the periportal lymph nodes. The bacilli can pass through the liver, however, into the main circulation through the patent foramen ovale. Alternatively, they can pass through the right ventricle into the pulmonary circulation, leading to a primary focus in the lung. The organisms in the lung often remain dormant until after birth when oxygenation and circulation increase significantly, leading to growth of organisms and pulmonary tuberculosis in young infants. In many children with congenital tuberculosis, multiple lesions occur throughout the body; it is impossible to determine if they represent multiple primary foci or if some occur secondary to primary lesions in the lung or liver. The only lesion of the neonate that is unquestionably associated with congenital infection is a primary complex in the liver with caseating hepatic granulomas [127,133].

Congenital infection of the infant also can occur through aspiration or ingestion of infected amniotic fluid [134]. If the caseous lesion in the placenta ruptures directly into the amniotic cavity, the fetus can inhale or ingest the bacilli. Inhalation or ingestion of infected amniotic fluid is the most likely cause of congenital tuberculosis if the infant has multiple primary foci in the lung, gut, or middle ear [135]. In congenital tuberculosis caused by aspiration, the primary complex can be in the liver, the lung, or both organs.

The pathology of congenital tuberculosis in the fetus and newborn usually shows the predisposition to dissemination ensured by the modes of transmission, particularly through the umbilical vein. The liver and lungs are the primary involved organs with bone marrow, bone, gastrointestinal tract, adrenal glands, spleen, kidney, abdominal lymph nodes, and skin also involved frequently [136,137]. The histologic patterns of involvement are similar to the patterns in adults; tubercles and granulomas are common. Central nervous system involvement occurs in fewer than 50% of cases [129,137]. In most more recent series, the mortality rate of congenital tuberculosis has been close to 50%, primarily because of the failure to suspect the correct diagnosis. Most fatal cases are diagnosed at autopsy [129,130].

Postnatal acquisition of *M. tuberculosis* through airborne inoculation is the most common route of infection of the neonate [138–140]. It may be impossible to differentiate postnatal infection from prenatal acquisition on clinical grounds alone [141]. Any adult in the neonate's environment can be a source of airborne tuberculosis, including health care workers [142,143]. Of infants with untreated *M. tuberculosis* infection, 40% develop tuberculosis disease within 1 to 2 years. There are few data concerning the time of onset of tuberculosis when the infection is acquired at or shortly after birth. It is estimated that 9% to 15% of mothers with tuberculosis transmit infection

to their infants in the postpartum period. Higher transmission rates are seen in mothers who are untreated or diagnosed late in pregnancy [97]. In one series of 48 infants exposed postnatally to mothers with pulmonary tuberculosis in the prechemotherapy era, 21 became infected; of infants who became ill, signs such as fever, tachypnea, weight loss, and hepatosplenomegaly developed in 4 to 8 weeks [144]. Because newborns infected with the organism are at extremely high risk of developing severe forms of disease, investigation of an adult with tuberculosis whose household contacts include a pregnant woman or newborn should be considered a public health emergency. In addition, all adults in contact with an infant suspected to have *M. tuberculosis* infection or disease should undergo a thorough investigation for disease.

The skin and mucous membranes are rare portals of entry for *M. tuberculosis* in neonates. Infection through the skin has been mentioned several times in association with lesions of the head and face, very likely related to minor traumatic lesions being infected by kissing. Primary lesions of the mucous membranes of the mouth also have been recognized, although usually in infants beyond the newborn period. In both of these situations, the primary lesion was insignificant, but the enlarged regional lymph nodes called attention to the problem [145].

A previously well-known form of skin and mucous membrane infection was tuberculosis of the male genitalia after circumcision in the years when it was customary for the individual performing the circumcision to suck the blood around the incision. This procedure was obviously dangerous if that individual happened to have bacilli in the sputum. The primary focus of inoculation on the penis was often inconspicuous, but within 1 to 4 weeks ulceration, suppuration, and bilateral inguinal lymphadenopathy would develop. At first firm and nontender, the nodes might later break down with sinus formation to the exterior. In his review of circumcision tuberculosis, Holt [146] described a case with extensive ulceration of the penis and scrotum, greatly swollen lymph nodes, a generalized rash resembling varicella, hepatosplenomegaly, fever, cough, rales, and a positive tuberculin test, with recovery of tubercle bacilli from sputum and penile discharge. Of the 41 patients described by Holt [146], 16 died and 6 recovered, with the outcome of the others unknown.

## CRITERIA FOR DIAGNOSIS OF CONGENITAL TUBERCULOSIS

In 1935, Beitzke [133] suggested the following criteria for diagnosis of congenital tuberculosis in a thoughtful, detailed, and often-quoted review of the reported cases up to that time:

1. Tuberculosis in the child must be firmly established.
2. A primary complex in the liver is proof of congenital tuberculosis because this complex could arise only through perfusion of the liver with tubercle bacilli contained in umbilical cord blood.
3. If a primary complex is lacking in the liver, tuberculosis can be considered to be congenital only if tuberculous lesions are present in a fetus or in a newborn only a few days old, *or*, in an older infant, extrauterine infection can be excluded with certainty—that is, if the infant was removed from the tuberculous mother at birth to a tuberculosis-free environment.

Cantwell and coworkers [127], based on a review of cases of congenital tuberculosis published before and after 1980, proposed a modification of Beitzke's criteria. The infant must have proven tuberculous lesions and at least one of the following: (1) lesions in the first week of life, (2) a primary hepatic complex or caseating hepatic granulomas, (3) tuberculosis infection of the placenta or maternal genital tract or both, or (4) exclusion of postnatal transmission by a thorough contact investigation. Although Beitzke's criteria are fully met by many of the approximately 350 reported cases of congenital tuberculosis, in other cases it is impossible to ascertain whether infection was transmitted in utero or was acquired during the early days or weeks of life. In many cases of true congenital tuberculosis, the mother was not known to have active tuberculosis.

Two articles contain tables with detailed information on 26 cases and 15 cases [129,130]. In only 10 of the 26 cases was tuberculosis diagnosed in the mother antepartum, although it became apparent in another 15 after diagnosis in the infant [129]. Five of the 26 mothers died of tuberculosis, an indirect confirmation of the fact that the diagnosis was made very late. In the series of 15 cases, 7 mothers were thought to be well at the time of delivery, but all 15 were subsequently found either to have had pleural effusion antepartum (four cases) or to have developed endometrial, miliary, or meningeal tuberculosis postpartum [130].

## CLINICAL FEATURES AND DIAGNOSIS OF CONGENITAL TUBERCULOSIS

The clinical manifestations of tuberculosis in the fetus and newborn vary in relation to the site and size of the caseous lesions. Symptoms may be present at birth, but more commonly begin by the 2nd or 3rd week of life. The most frequent signs or symptoms of true congenital tuberculosis are listed in Table 18–2 [127,129,147–177]. Most infants have an abnormal chest radiograph, with about half having a miliary pattern [178]. Some infants with a normal chest radiograph early in the course develop profound radiographic abnormalities as the disease progresses (Fig. 18–2). The most common abnormalities are adenopathy and parenchymal infiltrates. Occasionally, pulmonary involvement progresses very rapidly, leading to cavitation [179–181]. Tuberculosis of the middle ear in children with congenital tuberculosis has often been described [129,139,179,182–186]. The eustachian tube in newborns permits ready access to infected pharyngeal fluids or vomitus. Multiple perforations or total destruction of the tympanic membrane, otorrhea, enlarged cervical lymph nodes, and facial paralysis all are possible sequelae.

The clinical presentation of tuberculosis in a newborn is similar to bacterial sepsis [169–171] and congenital infections with syphilis and cytomegalovirus [14].

**TABLE 18–2** Most Frequent Signs and Symptoms of Congenital Tuberculosis

| Symptom or Sign | Frequency (%) |
|---|---|
| Hepatosplenomegaly | 76 |
| Respiratory distress | 72 |
| Fever | 48 |
| Lymphadenopathy | 38 |
| Abdominal distention | 24 |
| Lethargy or irritability | 21 |
| Ear discharge | 17 |
| Papular skin lesions | 14 |
| Vomiting, apnea, cyanosis, jaundice, seizures, petechiae | <10 each |

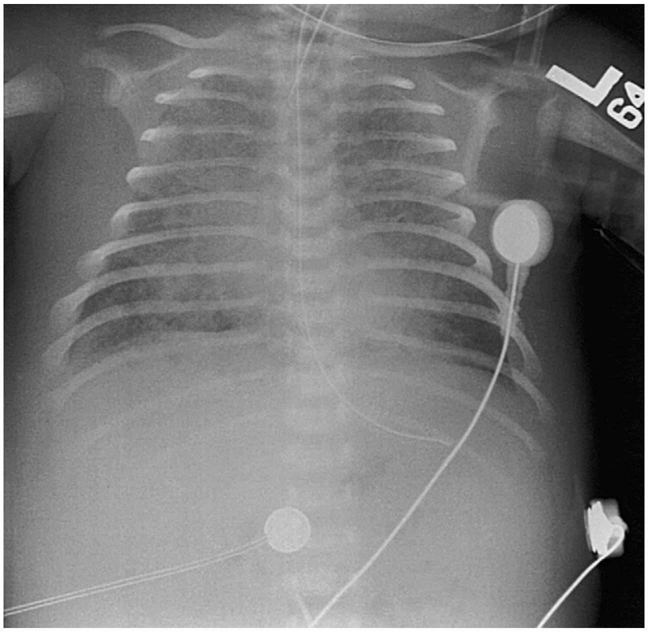

**FIGURE 18–2** Chest radiograph from a 1-month-old infant with congenital tuberculosis.

Abnormalities of liver function are common [172,174]. The diagnosis of congenital tuberculosis should be suspected in any infant with signs and symptoms of sepsis or viral infection who does not respond to vigorous antibiotic therapy and whose evaluation for other congenital infections is unrevealing. Suspicion also should be high if the mother has or has had tuberculosis, or if she is in a high-risk group for tuberculosis. The importance of obtaining an adequate history for the presence of risk factors for tuberculosis in the mother cannot be overemphasized. Suspicion should increase if the mother has had unexplained pneumonia, bronchitis, pleural effusion, meningeal disease, or endometritis during, shortly before, or even after pregnancy.

Evaluation of both parents and other family members can yield important clues about the presence of tuberculosis within the family. One study screened adult caregivers of children with suspected tuberculosis by chest radiograph and found that 15% of the screened adults had previously undetected pulmonary tuberculosis [187].

The timely diagnosis of congenital or neonatal tuberculosis is often difficult [125,188,189]. Whenever possible, the placenta should be examined and cultured for *M. tuberculosis*. The tuberculin skin test result is negative initially, although it may become positive after 1 to 3 months of treatment. There are no controlled trial data on the utility of interferon-γ release assays in infants. Two case reports in three infants with negative skin tests whose mothers had tuberculosis showed that the infants had positive interferon-γ release assays, facilitating appropriate therapy [190,191].

The diagnosis must be established by finding acid-fast bacilli in body fluids or tissue or by culturing *M. tuberculosis*. A positive acid-fast bacilli smear of an early morning gastric aspirate obtained from a newborn should be considered indicative of tuberculosis, although false-positive results can occur [13]. Direct acid-fast bacilli smears from middle ear fluid, bone marrow, tracheal aspirate, or biopsy tissue can be useful and should be obtained more often [174,192]. Hageman and colleagues [129] found positive cultures for *M. tuberculosis* in 10 of 12 gastric aspirates, 3 of 3 liver biopsy specimens, 3 of 3 lymph node biopsy specimens, and 2 of 4 bone marrow aspirations from children with congenital tuberculosis. Open lung biopsy also has been used to establish the diagnosis [193]. The cerebrospinal fluid should be examined and cultured, although the yield for isolating *M. tuberculosis* is less than 20%, and meningitis occurs in only one third of cases of congenital tuberculosis. There are no data addressing the utility of PCR for infants with tuberculous meningitis.

## TREATMENT OF TUBERCULOSIS

The drugs used most commonly to treat *M. tuberculosis* infection and disease, their dosage forms, and doses are listed in Table 18–3 [194]. Detailed discussion of the pharmacokinetics of each drug is beyond the scope of this chapter. No published study has examined in detail the pharmacokinetics of drugs used as antituberculosis agents in premature or term neonates [195].

INH is the mainstay of treatment for tuberculosis infection and disease in infants, children, and adults. It is inexpensive, highly effective in preventing the multiplication of tubercle bacilli, of low molecular weight and readily diffusible to all tissues in the body, and relatively nontoxic to children. It can be administered orally or intramuscularly. When INH is taken orally, high plasma, sputum, and cerebrospinal fluid levels are reached within a few hours and persist at least 6 to 8 hours. Because of the slow multiplication of *M. tuberculosis*, the total daily dose can be given at one time.

The principal toxic effects of INH are peripheral neuritis and hepatitis. Peripheral neuritis, resulting from competitive inhibition of pyridoxine, is almost unknown in North American children because cow's milk (and formula) and meat are the main dietary sources of pyridoxine. In some well-nourished children, serum

**TABLE 18–3** Antituberculosis Drugs in Children

| Drugs | Dosage Forms | Daily Dose (mg/kg) | Twice-Weekly Dose (mg/kg per dose) | Maximum Dose |
|---|---|---|---|---|
| Isoniazid | Scored tablets: 100, 300 mg | 10-15 | 20-30 | Daily: 300 mg |
| | Syrup: 10 mg/mL | | | Twice weekly: 900 mg |
| Rifampin | Capsules: 150, 300 mg | 10-20 | 10-20 | 600 mg |
| | Syrup: formulated in syrup from capsules | | | |
| Pyrazinamide | Scored tablets: 500 mg | 30-40 | 50 | 2 g |
| Streptomycin | Vials: 1, 4 g | 20-40 (IM) | 20-40 (IM) | 1 g |
| Ethambutol | Scored tablets: 100, 400 mg | 20 | 50 | 2.5 g |

*IM, intramuscular.*

pyridoxine concentrations are mildly depressed by INH, but clinical signs are not apparent. For most children, it is not necessary to use supplementary pyridoxine. In pregnant women, HIV-infected children and adolescents, teenagers whose diets may be inadequate, children from ethnic groups with a low milk and meat intake, and breast-fed infants, pyridoxine supplementation (25 to 50 mg/day) is important. Hepatotoxicity from INH is rare in children, increases in frequency with age, and is not preventable with pyridoxine supplementation. Monitoring serum aspartate aminotransferase and serum alanine aminotransferase sometimes reveals transient increases during treatment with INH, but the levels usually return spontaneously to normal without interruption of treatment. Liver enzyme abnormalities in adolescents receiving INH likewise are common and usually disappear spontaneously, but severe hepatitis can occur. Although neonates usually tolerate INH well, some experts recommend routine biochemical monitoring in the first several months of therapy.

The usual dosage of INH in children is 10 to 15 mg/kg daily (maximum dose 300 mg) or 20 to 30 mg/kg (maximum dose 900 mg) two or three times weekly (called intermittent). INH is available in scored tablets of 100 mg and 300 mg. A syrup of INH in sorbitol (10 mg/mL) seems to be satisfactory; however, it is unstable at room temperature and should be kept cool. Many children develop significant gastrointestinal intolerance (nausea, vomiting, diarrhea) while taking the INH suspension, but neonates and infants tolerate the lower required volume of suspension well. Changing from daily to intermittent therapy in young children should be carefully considered, however, because the incremental increase in medication volume may cause emesis. If tablets are used, they are easily crushed in a dessert spoon and given with some soft food such as mashed banana, thawed undiluted frozen orange juice, or another palatable medium. The crushed tablets should not be added to the nursing bottle or offered in milk or water because they would be ingested only partially.

Rifampin (RIF) is a semisynthetic drug derived from *Streptomyces mediterranei*. The drug is absorbed readily from the gastrointestinal tract in the fasting state. Excretion mainly is through the biliary tract; however, effective levels are achieved in the kidneys and urine. In many patients receiving RIF treatment, the tears, saliva, urine, and stool turn orange as a result of a harmless metabolite, and the patient and parents always must be warned of this in advance. RIF can be made into a suspension easily for use in children. RIF is very well tolerated by neonates and infants. The incidences of hepatitis, leukopenia, and thrombocytopenia are extremely low. RIF should be used alone only when treating *M. tuberculosis* infection caused by an INH-resistant organism. If one uses INH, 20 mg/kg, and RIF, 10 to 20 mg/kg (maximum daily dose 600 mg), there is an appreciable incidence of hepatotoxicity. When using the two together, one should approximate dosages of INH, 10 mg/kg, and RIF, 10 to 20 mg/kg.
